CHAPTER 21

Cerebral Palsy

Tara L. Johnson, Eric M. Chin, and Alexander H. Hoon, Jr.

Upon completion of this chapter, the reader will

- Understand the definition and causes of cerebral palsy
- Understand how cerebral palsy is diagnosed
- Know the clinical characteristics of the various forms of cerebral palsy
- Know the motor, sensory, cognitive, and medical problems commonly associated with cerebral palsy
- Understand the range of management options available to help children with cerebral palsy reach their full potential
- Be knowledgeable about the medical and functional prognoses for people with cerebral palsy

Many children with cerebral palsy (CP) first come to professional attention because of delays in early motor milestones, particularly rolling, crawling, standing and walking, or signs of early handedness. Most parents know that children begin walking at approximately 1 year of age, and there is an implicit understanding that a child's first steps mark the transition from infancy to toddlerhood. When a young child does not reach this transition at the expected time, alarm bells sound.

■ ■ ■ CASE STUDY

Jamal is a 15-month-old boy who was seen by his pediatrician for a routine well-child checkup. His mother expressed her worry that Jamal was not yet walking. His pediatrician had previously documented mild delays in motor development at the 12-month office visit. This

was attributed to the fact that he was born at 28 weeks' gestation, with a birth weight of 900 grams, following spontaneous labor that was associated with maternal **chorioamnionitis** (an infection of the membranes surrounding the fetus). In the neonatal intensive care unit (NICU), he required ventilatory support for 5 days. At 2 weeks of age, a cranial ultrasound study suggested an abnormality of brain white matter (see Chapter 5).

At his 12-month well-child checkup, his mother noted that Jamal had been sitting for about 2 months. His pediatrician explained that based on age adjustment for prematurity (9 months corrected age), he was only mildly delayed compared with chronological age expectations. Jamal's leg muscles were a little stiff, but his pediatrician knew that many premature infants have mild, temporary abnormalities of muscle tone that often resolve by 15–18 months of age.

On examination at 15 months, Jamal could crawl stiffly on all fours but was not yet pulling up to a standing position. He demonstrated a pronounced tendency to keep his legs stiffly extended with his toes pointed and his feet crossed at the ankles (scissoring). At this point, his pediatrician expressed her concern that Jamal was showing signs of CP.

Thought Questions:

If an infant is suspected of having CP, what are the most important initial steps that should be undertaken regarding medical testing and interventions? What types of accommodations should be considered in the school environment for a child with CP? How does this relate to type of CP and degree of motor impairment?

WHAT IS CEREBRAL PALSY?

CP describes a group of chronic childhood motor impairment disorders defined by specific functional characteristics rather than by the underlying cause. It was first described by William Little, an orthopedic surgeon who treated a child with spastic diplegia, a type of CP (Accardo, 1989). In 2006, CP was defined by an international consensus panel as follows:

Cerebral palsy describes a group of permanent disorders of the development of movement and posture causing activity limitation that are attributed to non-progressive disturbances that occurred in the developing fetal or infant brain. The motor disorders of cerebral palsy are often accompanied by disturbances of sensation, perception, cognition, communication, and behavior, by epilepsy, and by secondary musculoskeletal problems. (Rosenbaum et al., 2007, p. 9)

The hallmarks of CP are limitations in mobility and hand use with associated neuromotor abnormalities on physical exam. CP is characterized by impaired control of movement and posture that becomes evident early in life (Jacobsson et al., 2008). There is variability in overall motor function, often with associated impairments in sensation, cognition, communication, oromotor/gastrointestinal dysfunction, bowel/bladder function, and behavior. There may be visual impairment and epilepsy (Bax et al., 2005).

The clinical features of CP are the result of developmental disturbances that occur during early brain development, leading to brain malformation or injury. These disorders most often occur during fetal development or in the perinatal period, but they may also arise during the first years of life. Prematurity, low birth weight, multiple-gestation pregnancy, infection/inflammation, hypoxia-ischemia, and a variety of genetic

factors can act in concert, with the end result being CP (Pakula, Van Naarden Braun, & Yeargin-Allsopp, 2009).

Although CP is considered a static (“nonprogressive”) disorder, its functional manifestations can “progress” in several different ways. For example, children with early hypotonia (low muscle tone) associated with hypoxic-ischemic encephalopathy (HIE; previously referred to as “birth asphyxia”) may develop spasticity or dystonia years later (Scott & Jankovic, 1996). This may be the result of maladaptive plasticity (Johnston, 2009), wherein brain rewiring is misdirected or faulty. As another example, adults with dyskinetic forms of CP (see the Subtypes of Cerebral Palsy section) are prone to developing secondary spinal cord compression from long-term abnormal repetitive head and cervical spine movements. This leads to progressive weakness and loss of function (see Figure 21.1). Finally, there may be progressive orthopedic deformities secondary to spasticity, chronic muscle shortening, and joint dislocations, resulting in loss of motor function.

WHAT CAUSES CEREBRAL PALSY?

The underlying causes and risk factors leading to the development of CP disrupt the development of neuronal networks in the many brain pathways (cortical and subcortical) that control movement. Cortical regions of the brain include the frontal, temporal, parietal, and occipital lobes. Subcortical regions of the brain include the basal ganglia, thalamus, internal capsule, brain stem, and cerebellum (see Chapter 8).

A key concept in understanding the causes of CP is **selective vulnerability** (Johnston, 1998). This term refers to a susceptibility of specific regions and cells to injury during critical time periods in brain development. For example, the brain is structurally formed by approximately 12 weeks, and problems that occur during this time often lead to brain malformations such as holoprosencephaly, absence of the corpus callosum, and lissencephaly (see Chapter 6). From 24–34 weeks’ gestation, immature **oligodendrocytes** (brain cells that wrap myelin, a protective lipid-rich covering around axons) are susceptible to injury. Children who are born prematurely typically have spastic forms of CP, characterized by white matter injury around the ventricles, commonly termed periventricular leukomalacia (PVL), which is linked to oligodendrocyte injury.

This is in contrast with full-term infants, where the vulnerability lies in neurons in the basal ganglia and thalamus. A common cause of brain injury in the full-term neonate is perinatal HIE, which is defined as a disruption of blood flow (ischemia) and oxygen supply (hypoxia) to the brain at the time of birth (MacLennan, Nelson, Hankins, & Speer, 2010). Another cause

Figure 21.1. The white arrows point to areas of injury in the cervical spinal cord of two adults with dyskinetic (extrapyramidal) cerebral palsy (CP) as a result of cord compression from the chronic stress placed on the cervical spine (C-spine) from repetitive movement. These findings require emergent spinal fusion to stabilize the neck and to prevent the development of acute paralysis. Adults with CP and new neurological findings should have a brain magnetic resonance imaging (MRI) and C-spine MRI.

of brain injury in the neonate is kernicterus, which results from markedly elevated bilirubin levels after birth.

In term infants with HIE or kernicterus, the injury to neurons in these deep gray matter structures is often linked with dyskinetic (dystonic) forms of CP (see Figure 21.2). The recognition of selective vulnerability has led to new treatment approaches in the NICU setting, including the use of hypothermia (lowering body temperature) to ameliorate brain injury in term infants with HIE (Barks, 2008), as well as medications including xenon, erythropoietin, melatonin, and stem cell therapy (Douglas-Escobar & Weiss, 2015).

A common misconception is that most cases of CP result from HIE. It is now clear that birth asphyxia is the cause of CP in only 2%–10% of affected children (Eunson, 2012). This new observation confirms Freud's observation:

Difficult birth and premature birth are not always accidental happenings, but may frequently be results of a deeper cause, or its expressions, without being the actual etiological factor. Thus it may well be possible that the same pathogenic factors that rendered intra-uterine environment abnormal also extended their influence to parturition; abnormal birth is then the final result of abnormal pregnancy. (Freud, 1897)

Figure 21.2. The selective vulnerability of specific regions in the brain in infants born at term with asphyxia. A) The white arrow points to injury in the putamen; the black arrow points to injury in the thalamus. B) The white arrows point to injury in the motor cortex. This pattern of injury often leads to dyskinetic (dystonic) cerebral palsy (CP), with limitations in speech and hand use.

A key concept in effectively treating children with CP is the recognition that understanding the underlying cause can serve as a foundation to improve overall management. Understanding the mechanism of injury and the resultant clinical phenotype leads to the recognition of commonly correlated patterns on neurologic examination. For example, prematurity predisposes an infant to PVL, which can result in spastic diplegia, whereas a full-term infant with CP may have basal ganglia involvement, which can result in dyskinetic (athetoid or dystonic) CP.

Approaching diagnosis with an appreciation that neurologic examination findings typically correspond with clinical history enables the identification of other motor disorders that do not fit such patterns. These include rare, but often treatable, genetic disorders such as dopa-responsive dystonia, which can be improved with levodopa (Mink, 2003); mitochondrial disorders (Koene & Smeitink, 2009), some of which can be treated with specially tailored vitamin preparations; and organic acidemias (Seashore, 2009), which may be treatable with special metabolic formulas (see Chapter 16).

Etiology refers to the underlying cause for a disorder, such as CP secondary to brain injury associated with preterm birth. Etiologic diagnosis is also of benefit in establishing both prognosis and recurrence risk of CP or other motor disorders that mimic CP. This knowledge can provide information to families as they contemplate future pregnancies (Hemminki, Li, Sundquist, & Sundquist, 2007). The discovery of genetic etiologies is also emerging, and it may provide insight regarding inherited risk factors for CP (Moreno-DeLuca, Ledbetter, & Martin, 2012).

EPIDEMIOLOGY

In the developed world, CP affects about 2 in 1,000 children (Christenson et al., 2014; Himmelfmann, Hagberg, & Uvebrant, 2010). CP is most commonly associated with prematurity and low birth weight. Approximately 50,000 infants who are very low birth weight (less than 1,500 grams) are born in the United States each year, of whom 10%–15% develop spastic CP and 20%–50% develop disorders of higher cortical function, including ADHD, learning disabilities, and intellectual disability (Volpe, 2005). The incidence of CP also increases with decreasing gestation and may occur in up to 28% of infants born before 26 weeks' gestation (Eunson, 2012).

Despite advances in perinatal management over the last 20–30 years, the incidence of CP in term infants has not changed. This is consistent with the understanding

that CP in full-term infants most commonly results from prenatal insults or genetic conditions that are independent of, or may operate in conjunction with, factors associated with delivery (Fahey, MacLennan, Kretschmar, Gecz, & Kruer, 2017).

In developing countries, accurate epidemiological estimates have been difficult to obtain, but overall prevalence appears to be similar to that in developed countries. Small uncontrolled hospital-based studies suggest an increased proportion attributed to perinatal and postneonatal etiologies (e.g., meningitis, kernicterus, trauma, and hypoxic injury) and a decreased proportion associated with prematurity and low birth weight. Accordingly, a greater proportion of quadriplegia has been reported (Colver, Fairhurst, & Pharoah, 2014; Gladstone, 2010).

RISK FACTORS

Infection

Both indirect infections (passed from the mother) and direct infections (of the fetus or newborn infant) have been shown to be associated with CP (Bale, 2009). In term and preterm infants, direct infection of the fetus by viruses such as cytomegalovirus and rubella (Lombardi, Garofoli, & Stronati, 2010) and other infectious agents (e.g., toxoplasmosis, a parasitic infection) has long been a recognized cause of CP. More recently, microcephaly and CP have also been associated with Zika virus (Pessoa et al., 2018). Bacterial meningitis in the newborn also remains a significant cause of CP (Galiza & Heath, 2009).

There is increasing recognition that chorioamnionitis plays a key role in the development of CP in preterm infants (Shatrov et al., 2010). Chorioamnionitis predisposes to premature delivery and may also have direct adverse effects on the fetal brain (Jacobsson, 2004; Yoon, Park, & Chaiworapongsa, 2003). Complex relationships exist among chorioamnionitis, fetal **cytokines** (proteins that regulate the immune response), and other inflammatory factors that, depending on timing, can predispose toward brain injury or can trigger a protective response. The former can lead to cortical or white matter injury in children born preterm (Hagberg et al., 2015).

In the term infant, there is an association among maternal infection, fever, and CP (Nelson & Chang, 2008). Infection during pregnancy may also promote blood hypercoagulation, leading to stroke-like events in the fetus (Leviton & Dammann, 2004; Nelson & Lynch, 2004). Finally, placental abnormalities may contribute to the development of HIE, perinatal stroke, low Apgar scores, and term stillbirth (McIntyre et al., 2015; Wu, 2002).

Prematurity-Related Cerebral Palsy

Premature infants, especially those born prior to 28–32 weeks' gestation or with a birth weight less than 1,500 grams, represent almost half of all individuals with CP (Eunson, 2012). The increased risk of CP in premature infants is related to complex interrelations between destructive and developmental mechanisms (Volpe, 2009).

In premature infants, the two most common types of injury are PVL (see Figure 21.3) and periventricular-intraventricular hemorrhage (PIVH; see Chapter 5). Immaturity of brain development predisposes premature infants to both of these conditions.

In the late 1970s to early 1980s, cranial ultrasound and computed tomography linked CP with brain hemorrhage. In the later 1980s to early 1990s, the advent of magnetic resonance imaging (MRI) vividly confirmed that the major injury was in cerebral white matter. Since the late 2000s, more-detailed MRI studies have shown that the white matter injury is accompanied by diffuse, variable injury in cortical, subcortical, and cerebellar gray matter (Kusters, Chen, Follett, & Dammann, 2009; Reid et al., 2015).

Volpe (2005) demonstrated that the abnormalities in neurons and axons are the result of changes in the normal developmental trajectory of brain development, often initiated by hypoxic-ischemic or infectious/inflammatory cascades of injury. These disturbances may explain the complex patterns of motor, learning, intellectual, and neurobehavioral impairments encountered in affected children.

Finally, in children such as Jamal, there is evidence—using the advanced MRI imaging technique of diffusion tensor imaging (DTI; see Chapter 8), which shows white matter tracts—that functional impairment

may result from injury to both sensory and motor cortical pathways (Hoon et al., 2009; Nagae et al., 2007; see Figure 21.4).

Cerebral Palsy in Full-Term Infants

A wide variety of prenatal, perinatal, and genetic factors are linked with CP in full-term infants. These include HIE, congenital brain malformations, coagulation abnormalities, complications related to multiple-gestation pregnancies, and intrauterine infection/inflammation (Jacobsson et al., 2008; Nelson, 2008). Compared with those born prematurely, full-term infants who subsequently develop CP are more likely to be small for gestational age or have malformations inside and outside of the central nervous system (CNS), suggesting problems in early brain development (Krägeloh-Mann et al., 1995).

In full-term infants with severe HIE, who often develop dyskinetic CP, the injury is often in the basal ganglia located deep in the center of the brain (Himmelman et al., 2009). In the past, high bilirubin levels in the immediate postnatal period resulted in kernicterus, which led to choreoathetoid CP and to hearing impairment. Although kernicterus is rare now in developed countries, more subtle bilirubin-induced neurologic dysfunction continues to be a concern (Shapiro, 2005).

DIAGNOSIS

CP is diagnosed clinically; it is suspected by the presence of delays in motor development and confirmed by distinct abnormalities on neurological examination. Although newborns may have known risk factors for CP (e.g., PVL or HIE), CP cannot be diagnosed at

Figure 21.3. This MRI was taken in childhood from a child with periventricular leukomalacia who had spastic quadriplegia. The arrows point to areas of injury or destruction of brain white matter (wiring). The enlarged ventricles (ventriculomegaly) are secondary to loss of surrounding brain tissue. (Adapted with permission from Wolters Kluwer: *Journal of Developmental and Behavioral Pediatrics*. Hoon, A.H., & Melhem, E.R. Neuroimaging: Applications in disorders of early brain development. 21, 291–302. [2000])

Figure 21.4. Using diffusion tensor imaging (DTI) and tract reconstruction software, three-dimensional images of descending motor pathways (light gray fibers) and thalamocortical sensory tracts (black fibers) are shown in a typically developing child (left panel) and in two children with spastic cerebral palsy in association with periventricular leukomalacia (PVL) (middle and right panels). In the children with PVL, the primary injury is seen as a decrease in black fibers, which transmit sensory information from the thalamus to the cortex. (Adapted with permission from Nagae, L.M., Hoon, Jr., A.H., Stashenko, E., Lin, D., Zhang, W., Levey, E., . . . Mori, S. [2007]. Diffusion tensor imaging in children with periventricular leukomalacia: Variability of injuries to white matter tracts. *AJNR: American Journal of Neuroradiology*, 28[7], pp. 1213–1222.)

birth because the characteristic diagnostic signs are not apparent this early. Using traditional neurological physical exam findings, children with severe forms of CP are usually diagnosed in the first year of life, while those with less severe forms are usually diagnosed during the second year (Aneja, 2004; Palmer, 2004; Russman & Ashwal, 2004).

Early detection of CP is becoming increasingly widespread, with emerging evaluation tools such as Prechtl's General Movement Assessment (General Movements Trust, 2009), which has been shown to be predictive of future motor dysfunction and comorbidities in neonates and infants (Einspieler, Bos, Libertus, & Marschik, 2016; Einspieler & Prechtl, 2005; General Movements Trust, 2009). General movements are a means to evaluate the integrity of the immature nervous system, and they are thought to result from central pattern generators. Such movements include writhing movements, which occur from early fetal life to 6–9 weeks post term, and fidgety movements, which occur from 3–5 months post term. In general, variability of movements is a favorable prognostic sign. Ideally, early detection of CP would promote the institution of intervention at a younger age, and the child would receive increased benefit from the provision of such therapies.

One of the key features of CP is the persistence of primitive reflexes. All infants are born with primitive reflexes. They are called “primitive” because they are present in early life (in some cases, during intrauterine development) and are thought to be controlled by the spinal cord, labyrinths of the inner ear, and the brain stem (the primitive areas of the CNS). Familiar

examples of primitive reflexes include the suckling reflex and the hand-grasp reflex in the newborn. As the cortex matures, these reflexes are gradually suppressed and integrated into voluntary movement patterns (see Figure 21.5). The process of integration is usually complete by 12 months of age. In CP, however, these primitive reflex patterns tend to persist beyond early infancy. Among the primitive reflexes, the **asymmetric tonic neck reflex** (Figure 21.6) and the **tonic labyrinthine response** (Figure 21.7) are particularly helpful in the diagnosis of CP.

As primitive reflexes disappear in the typically developing child, **postural reactions** (also known as

Figure 21.5. The time course of primitive reflexes, postural reflexes, and volitional motor activity in typical motor development. (From Capute, A. J., Accardo, P. J., Vining, E. P. G., Rubenstein, J. E., & Harryman S. [1978]. *Primitive reflex profile*. Baltimore, MD: University Park Press; reprinted by permission.)

Full-term Infant
Resting PositionAsymmetrical Tonic
Neck Reflex

Figure 21.6. The asymmetric tonic neck reflex. In the typical newborn infant, when the head is actively or passively turned to the side, the arm and leg on the same side will extend and the arm and leg on the opposite side will flex, resulting in a “fencing” posture. The opposite pattern occurs when the head is turned to the other side. In typically developing infants, the reflex fades (is integrated) by about 6 months of age and is never obligatory (the infant can break through the pattern with spontaneous movement, even in the newborn period). In children with cerebral palsy, the reflex tends to be more pronounced, persists beyond the expected age, and may be obligatory.

automatic movement reactions) emerge (Figure 21.8). Some of the more important of these reactions are the righting, equilibrium, and protective reactions, which enable the child to develop more complex voluntary movement and better control of posture. The emergence of postural reactions along with the simultaneous disappearance of primitive reflexes are essential precursors for the development of specific motor milestones, such as rolling over and sitting.

In typically developing children, a protective reaction called the parachute response develops by 10–12 months of age. This reaction is manifested by forward extension of the arms when falling forward. Many children with CP have delayed or absent development of postural reactions, including this response, which makes sitting or walking difficult. CP may be viewed as the persistence of primitive reflexes combined with the lack of cortical maturation of postural reactions.

The neurological examination of the motor system is an important tool to characterize an individual's type of CP. Neurological exam findings can be divided into two categories: those that can be seen and those that can be felt (see Figure 21.9). For example, one can observe dystonia, or twisting postures, simply by watching the patient. However, to appreciate spasticity, one must lay hands on the patient and assess the effects of joint motion on resistance to movement (Sanger, Delgado, Gaebler-Spira, Hallett, & Mink, 2003).

Upper Motor Neuron Dysfunction in Cerebral Palsy

The motor impairments in children with CP are secondary to injury in the upper motor neuron (UMN). The UMN system is not a discrete anatomical entity but

Figure 21.7. The tonic labyrinthine reflex. A) When the child is in the supine position with the head slightly extended, retraction of the shoulders and extension of the legs is observed. B) The opposite occurs when the infant is in the prone position with the head slightly flexed. In typically developing infants, the reflex pattern is barely evident in the newborn period; in children with cerebral palsy, the pattern may dominate posture and movement and may persist throughout life.

Figure 21.8. Automatic movement responses: the lateral prop reaction. At about 6 months of age, typically developing infants have already developed good postural control of the head and trunk (righting or equilibrium responses) and can stop themselves from falling forward when placed in the sitting position by extending their arms in front of them (forward prop response). By 6 months of age, most infants can also catch themselves when falling to the side by extending the arm on the same side (lateral prop response). This automatic movement reaction is critical for independent sitting and may be delayed or absent in children with cerebral palsy. (From Pellegrino, L., & Dormans, J. P. [1998]. Making the diagnosis of cerebral palsy. In J. P. Dormans & L. Pellegrino [Eds.], *Caring for children with cerebral palsy: A team approach* [p. 39; portion of Figure 2.4]. Baltimore, MD: Paul H. Brookes Publishing Co., Inc.; reprinted by permission.)

refers collectively to the motor control systems based in the brain and spinal cord. The UMN system is distinguished from the lower motor neuron (LMN) system, which refers collectively to the peripheral nerves and the innervated muscles (Figure 21.10; see Chapter 8). The primary components of the UMN system are the **pyramidal tract** (also called the **corticospinal pathways**) and the extrapyramidal system (see Figure 21.11). These systems are differentially affected by disturbances to the developing brain.

UMN dysfunction is characterized by positive and negative signs. Positive signs include spasticity, **hyper-reflexia** (increased deep tendon reflexes; e.g., the knee jerk), **clonus** (alternate involuntary muscular contraction and relaxation in rapid succession), **upper limb flexor and lower limb extensor spasms** (spasms of bending of a limb toward or away from the body), and a positive **Babinski sign** (upgoing toe when the sole of

Seen (Observed)	Felt (Palpated)
<i>Dystonia</i> : twisting postures	<i>Spasticity</i> : velocity-dependent resistance
<i>Chorea</i> : dance-like movements	<i>Rigidity</i> : co-contraction
<i>Athetosis</i> : slow, writhing movements	<i>Hypotonia</i> : decreased tone
<i>Ataxia</i> : gait, titubations (bobbing head movements)	<i>Muscle consistency</i> : atrophy in myopathy

Figure 21.9. Elements of the neuromotor examination. The neuromotor examination can be categorized by those findings that can be simply observed and those findings that require palpation. Assessment of movement quality can be characterized by size and speed of movement. Tone is defined as resistance to passive stretch. In spasticity, tone increases as a function of increasing velocity. At high velocities, a clasp-knife phenomenon occurs, with a “catch” that can be felt by the examiner. Rigidity is defined as a lead pipe feel and occurs secondary to co-contraction of opposing muscle groups.

Figure 21.10. The location of upper and lower motor neurons. Low motor neuron dysfunction is associated with peripheral neuropathies. (From Shrestha, S. [2010]. Lesions of upper motor neurons and lower motor neurons. *Medchrome Online Medical Magazine*. Retrieved from <http://medchrome.com/basic-science/anatomy/lesions-of-upper-motor-neurons-and-lower-motor-neurons>; reprinted by permission.)

the foot is stroked firmly). Negative signs include muscle weakness, loss of manual dexterity, and fatigability. The profile of positive signs tends to vary more from child to child, and this contributes to the classification of the subtypes of CP. It is the negative signs, however, that more directly impede motor function (Sanger et al., 2006).

Walking

When a child is diagnosed with CP, one of the first questions parents pose is, “Will he or she walk?” In addressing this question, it is important to recognize that “walking” can refer to several levels of ability. A child may be able to walk independently or may need crutches or a walker. A child may be able to walk long distances (community ambulation), short distances only (household ambulation), or solely in the context of therapy (exercise ambulation). In general, children with better motor skills at a younger age (e.g., being able to sit and pull-to-stand before 2 years of age) have a better prognosis for walking than those with less well-developed skills.

Jamal, who we met in the case study at the beginning of this chapter, was sitting independently at 10 months of age, and there was concern that he was not yet walking by 15 months of age. A number of functional assessment systems have been developed to

Figure 21.11. The motor control system. The upper motor neuron system consists of the pyramidal and extrapyramidal systems. The pyramidal system connects the motor control center of the cortex to the brainstem and spinal cord and is responsible for the direct control of movement and muscle tone. The extrapyramidal system consists of deep brain structures (especially the basal ganglia and cerebellum) and works primarily by modifying and refining the output of the pyramidal system. The lower motor neuron system consists of neuronal pathways from the spinal cord to the innervated muscles, including nerves that regulate the stretch reflex mechanism. (From Pellegrino, L., & Dormans, J. P. [1998]. Definitions, etiology, and epidemiology of cerebral palsy. In J. P. Dormans & L. Pellegrino [Eds.], *Caring for children with cerebral palsy: A team approach* [p. 10]. Baltimore, MD: Paul H. Brookes Publishing Co., Inc.; reprinted by permission.)

predict walking (Oeffinger et al., 2004; Palisano et al., 1997; see Table 21.1). The Gross Motor Function Classification System—Expanded and Revised (GMFCS–E&R; Palisano, Cameron, Rosenbaum, Walter, & Russell, 2006) is often helpful for planning therapeutic interventions and establishing goals for habilitation. It is more predictive of long-term functional outcome than traditional, impairment-focused classification schemes (Palisano et al., 2007).

The GMFCS can be used to guide prognosis for walking (Rosenbaum et al., 2002; Wood & Rosenbaum, 2000). Children at any level within the classification scheme tend to stay at or move slightly below that level as they reach adolescence and adulthood (Hanna et al., 2009). In general, children at GMFCS levels I or

II will have a good prognosis for some degree of independent ambulation and will retain their functionality into adulthood. Children at levels III and IV will have a variable prognosis for walking with some form of assistance and may decline functionally when they reach school age, and children at level V have a poor prognosis for any type of walking.

Precise probability curves for ambulation have been published that allow even more exact predictions of ambulatory potential based on motor functioning at 2½ years of age (Wu, Day, Strauss, & Shavelle, 2004). For example, using these curves, it can be predicted that a child who is able to roll, sit independently, and pull-to-stand at 2½ years of age has a greater than 70% probability of being able to

Table 21.1. Summary of the Gross Motor Function Classification System–Expanded and Revised (GMFCS-E&R)

Level	Age				
	<2 years	2–4 years	4–6 years	6–12 years	12–18 years
I: Walks without limitations	Sits well (hands free to play), crawls and pulls-to-stand; walks between 18 and 24 months without a device	Gets up and down from floor to standing without help; walking is preferred method of mobility	Walks indoors and outdoors; climbs stairs; starting to run/jump	Independent walking, running, jumping, but speed, balance, and coordination are limited; may choose to participate in sports	Independent walking, running, jumping; may choose to participate in sports
II: Walks with limitations	Sits but may need hands for balance; may creep or crawl; may pull-to-stand or cruise	Floor sits, but hard to keep both hands free; mobility by crawling, cruising, or walking with assistive device	Transfers with arm assist; walks without device at home, short distances outside; climbs stairs with railing; no running or jumping	Independent walking but limitations in challenging circumstances; minimal running, jumping	Independent walking but limitations in challenging circumstances; may use hand-held mobility device at school; may use wheeled mobility for long distances
III: Walks using a hand-held mobility device	Sits with low back support; rolls and creeps	Floor sits, often W-sitting, needs help getting to sit; creeping and crawling primary means of mobility; limited assisted standing/walking	Sits in regular chair with pelvic support to allow free hands; walks with device on level surface; transported for long distances	Walks indoors or outdoors with hand-held mobility device; wheeled mobility transport for long distances	Variable use of hand-held mobility device; self-propelled wheel chair or powered mobility at school; powered mobility or wheelchair transport for long distances
IV: Self-mobility with limitations; may use powered mobility	Has head control, but needs trunk support for sitting; rolls to back; may roll to front	Needs hands to maintain sitting; adaptive equipment for sitting/standing; floor mobility only (rolling, creeping, or crawling without reciprocal leg movements)	Adaptive seating needed for maximum hand function; needs assistance for transfers; walks short distances with assistance; power mobility for long distances	Maintains function achieved by ages 4–6 or relies more on power wheelchair for self-mobility; powered mobility or wheelchair transport for long distances	Use wheel mobility in most settings; physical assistance from 1–2 people needed for transfers (may be able to support weight on legs); powered mobility or wheelchair transport for long distances
V: Transported in a manual wheelchair	Limited voluntary control of movement; head and trunk control minimal; needs help to roll	Limited control of movement and posture; all areas of motor function are limited; adaptive equipment does not fully compensate for functional limitations in sitting and standing; no independent mobility (requires transport); some children and youth achieve very limited power mobility with extensive adaptations; older children and youth require 1–2 people or mechanical lift for transfers			

Source: Palisano, Cameron, Rosenbaum, Walter, and Russell (2006).

engage in some form of ambulation by age 7 years. By contrast, a child who can roll but cannot sit or pull-to-stand at 2½ years has only a 25% chance of walking and would most likely do this with the help of an assistive device.

To walk, a child must be able to maintain an upright posture, move forward in a smoothly coordinated manner, and demonstrate protective responses for safety when falling. Even a child with mild CP has

difficulty with the neurologic motor control required for ambulation. Common, treatable problems affecting gait include scissoring and an equinus position of the feet. Scissoring occurs because of increased tone in the muscles that control adduction (movement toward the midline) and internal rotation of the hips. Toe walking results from an equinus position of the feet (Figure 21.12) and increased extensor tone in the legs.

Figure 21.12. Scissoring results from increased tone in the muscles on the inner aspect of the thigh that tend to pull the legs together and turn the legs inward. Toe walking is due to tightness of the calf muscles and Achilles tendon and increased extensor tone in the legs.

Children with CP may also have fine motor impairment, which can be quantified by the Manual Ability Classification System (MACS). A child with MACS level I can handle objects easily and successfully,

whereas a child with MACS level V does not handle objects and has severely limited manual dexterity (see Table 21.2; Eliasson et al., 2006).

Children with CP may also have oromotor impairment, which can be quantified by the Eating and Drinking Ability Classification System (EDACS; see Table 21.3). A child with EDACS level I eats and drinks safely and efficiently, while a child with an EDACS level V is unable to eat or drink safely and may require tube feeding for nutritional support (Sellers, Mandy, Pennington, Hankins, & Morris, 2014).

The International Classification of Functioning, Disability, and Health (ICF) is a multidimensional way to classify functioning and disability in the context of medical and environmental domains (WHO, 2001, 2007; see Chapter 32, specifically Figure 32.1). When applying the ICF model to Jamal, the 15-month-old boy with delayed walking, his health condition can be defined as CP and his symptoms are consistent with spastic diplegia secondary to PVL. His body functions and structures can be described as bilateral stiffness and weakness of all extremities, with legs more affected than arms. His *activity* can be described as difficulty with walking, more specifically that he may develop into a child who is a household or community ambulator. One way in which his *participation* may be affected now is the limited options for child care

Table 21.2. Measures of manual dexterity

Ages	Mini-MACS (adapted from Eliasson et al., 2017)	Manual Ability Classification System (MACS) (adapted from Eliasson et al., 2006)
	1–4 years	4–18 years
Level I	Handles objects easily and successfully. At most limitations in the ease of performing manual tasks requiring speed and accuracy.	Handles objects easily and successfully. At most, limitations in the ease of performing manual tasks requiring speed and accuracy. However, any limitations in manual abilities do not restrict independence in daily activities
Level II	Handles most objects, but with somewhat reduced quality and/or speed of achievement. Some actions can only be performed and accomplished with some difficulty and after practice. The child may try an alternative approach, such as using only one hand. The child needs adult assistance to handle objects more frequently compared to children at the same age.	Handles most objects but with somewhat reduced quality and/or speed of achievement. Certain activities may be avoided or be achieved with some difficulty; alternative ways of performance might be used, but manual abilities do not usually restrict independence in daily activities.
Level III	Handles objects with difficulty. Performance is slow, with limited variation and quality. Easily managed objects are handled independently for short periods. The child often needs adult help and support to handle objects.	Handles objects with difficulty; needs help to prepare and/or modify activities. The performance is slow and achieved with limited success regarding quality and quantity. Activities are performed independently if they have been set up or adapted.
Level IV	Handles a limited selection of easily managed objects in simple actions. The actions are performed slowly, with exertion and/or random precision. The child needs constant adult help and support to handle objects.	Handles a limited selection of easily managed objects in adapted situations. Performs parts of activities with effort and with limited success. Requires continuous support and assistance and/or adapted equipment for even partial achievement of the activity.
Level V	Does not handle objects and has severely limited ability to perform even simple actions. At best, the child can push, touch, press, or hold on to a few items in constant interaction with an adult.	Does not handle objects and has severely limited ability to perform even simple actions. Requires total assistance.

Table 21.3. Eating and Drinking Ability Classification System for Individuals with Cerebral Palsy (EDACS; adapted from Sellers et al., 2014)

Level I	Eats and drinks safely and efficiently
Level II	Eats and drinks safely but with some limitations to efficiency
Level III	Eats and drinks with some limitations to safety; maybe limitations to efficiency
Level IV	Eats and drinks with significant limitations to safety
Level V	Unable to eat or drink safely—tube feeding may be considered to provide nutrition

environments that will meet both his cognitive and physical needs. *Environmental factors* may be positive, such as his caring parents; alternatively, they may be barriers, such as stairs in the home. *Personal factors* are that he is a 15-month-old boy, that he has access to early intervention services, and that he is growing up in a stimulating environment.

SUBTYPES OF CEREBRAL PALSY

CP is often divided into specific **phenotypes** (physical appearances) according to the neurological findings and body limbs that are predominantly affected (Koman, Smith, & Shilt, 2004; Figure 21.13). A recognized classification system divides the phenotypes into bilateral (both sides of the body affected) and unilateral (one side affected). This distinction is useful both in evaluating the underlying cause as well as directing management of CP (Rosenbaum, 2007).

Spastic Cerebral Palsy

Spasticity is the abnormal increase in muscle tone resulting from an increased resistance to muscle stretch and lengthening. It restricts voluntary movement and, over time, leads to contractures (Barnes & Johnson, 2008). Spasticity is believed to arise from disruption of the descending pathways involved in motor control, including both pyramidal and parapyramidal pathways. The pyramidal system (i.e., the corticospinal tract) is composed of neurons that extend from the motor cortex to the brainstem and spinal cord. These pathways directly control movement and influence muscle tone and deep tendon reflexes by inhibiting spinal cord mechanisms that direct these processes. In the absence of normal corticospinal inhibition, the spinal cord influences predominate, resulting in spasticity and a positive Babinski sign, two of the hallmarks of spastic CP. The parapyramidal fibers from premotor cortex also contribute to spasticity and UMN signs.

Spastic CP is the most common type of CP (Krägeloh-Mann & Cans, 2009). It is further categorized according to the distribution of limbs involved. In **spastic diplegia**, the legs are more affected than the arms.

This is the type of CP most frequently associated with prematurity. In **spastic hemiplegia**, one side of the body is more affected than the other; usually, the arm is more affected than the leg. Because the motor neurons that control one side of the body are located in the opposite cerebral cortex, a right-sided hemiplegia implies injury to the left side of the brain, and vice versa. In **spastic quadriplegia**, all four limbs and usually the trunk and muscles that control the mouth, tongue, and pharynx are affected. The severity of the motor impairment in spastic quadriplegia implies wider cerebral dysfunction and a poorer outcome than for the other forms of spastic CP. Individuals with spastic quadriplegia often have intellectual disability, seizures, sensory impairments, and other medical problems.

Dyskinetic Cerebral Palsy

Children who have CP as a consequence of disturbances in the extrapyramidal system exhibit atypical movements known as **dyskinesias** (CP Family Network, 2012). These include chorea, athetosis, choreoathetosis, and dystonia. Rapid, random, jerky movements are known as **chorea**; slow, writhing movements that appear to flow into one another are called **athetosis**. When seen together, these movements are called **choreoathetosis**. **Dystonia** refers to repetitive, twisting movements and distorted postures.

Dyskinetic CP (also known as extrapyramidal CP) is characterized by abnormalities in muscle tone that involve the whole body. Changing patterns of tone from hour to hour and day to day are common. These children exhibit increased muscle tone, especially during attempted movement, and normal or decreased tone while asleep. The term athetoid CP characterizes a form of dyskinetic CP that has been associated with kernicterus. Dystonic CP is associated with hypoxic-ischemic encephalopathy as well as with a wide range of genetic disorders. Chorea is the least common form of dyskinetic CP.

Ataxic Cerebral Palsy

Ataxia results from an abnormality in the cerebellum and manifests as the inability to maintain typical

TYPE	Spastic			Dyskinetic	Ataxic
	Unilateral (30%)*	Bilateral (58%)		(7%)	(4%)
SUBTYPE	Hemiplegia	Diplegia	Quadriplegia		
Distribution					
	Asymmetric; arms/hands often more affected than legs	Symmetric; legs mainly affected, mild difficulties with arms/hands	Both side of the body involved (including head & trunk); may be symmetric or asymmetric	Both sides of the body involved (including head & trunk); symmetric	Both sides of the body involved (including head & trunk); symmetric
Clinical Features	Increased tone Increased reflexes (evidence of <i>spasticity</i>) Predominantly one side of the body affected (arm/hand often more than leg) Development of contractures with time	Increased tone Increased reflexes (evidence of <i>spasticity</i>) Both sides of the body affected (legs more than arms/hands) Development of contractures with time	Increased tone Increased reflexes (evidence of <i>spasticity</i>) Both sides of the body affected with significant variation in the degree of involvement of different limbs Development of contractures with time	Variable tone Reflexes normal or slightly increased Both sides of the body affected Associated with involuntary movements: <i>athetosis</i> (slow, writhing movements), <i>chorea</i> (rapid, jerking movements) and/or <i>dystonia</i> (posturing movements)	Low tone Reflexes normal or slightly increased Both sides of the body affected Associated with <i>ataxia</i> (poor balance, tremors, poorly graded voluntary movements)
Periventricular damage	++	+++	++	+	? (insufficient data)
Cortical or deep brain (basal ganglia) damage	++	+	+++	+++	? (insufficient data)
Congenital malformations	+	+	+	---	++ (especially of the cerebellum)
Infants affected	Mainly Term, some Preterm	Mainly Preterm	Term and Preterm	Mainly Term	Mainly Term

* Percentage of all types of CP; percentages do not include mixed forms of cerebral palsy, or forms for which a subtype is undefined.

Figure 21.13. The subtypes of cerebral palsy (CP). The spastic forms of CP are most common and can involve both sides of the body (diplegia and quadriplegia) or may mainly involve one side of the body (hemiplegia). Diplegia mainly involves the lower extremities and is the most common form of CP associated with periventricular (PV) injury related to prematurity. Quadriplegia involves the whole body and is most often due to hypoxic-ischemic (HI) injury in term infants or PV injury in preterm infants. Hemiplegia may be caused by PV injury but is also commonly caused by prenatal and postnatal stroke (resulting in damage to the cortex on one side). Dyskinetic forms of CP involve the whole body, are associated with involuntary movements, and may be caused by damage to the basal ganglia (deep brain structures) due to HI injury or by newborn jaundice associated with very high levels of bilirubin (kernicterus); it has also been associated with several genetic disorders. Ataxic CP involves the whole body and is associated with problems with balance, tremors, and difficulties with finely graded voluntary movements. The causes of ataxic CP are poorly understood, but it has been associated with congenital abnormalities of the cerebellum. (Source: Krägeloh-Mann & Cans, 2009.)

postures and perform typical movements. As a result, movements are jerky and uncoordinated, without the smooth flow of typical motion (CP Family Network, 2012). Ataxic CP is characterized by impairments in voluntary movement, involving balance and position of the trunk and limbs in space. For children who can walk, this is manifested as a wide-based, unsteady gait. Difficulties with controlling the hand and arm during reaching (causing overshooting or past-pointing) and difficulties with the timing of motor movements are also observed. Ataxic CP may be associated with either increased or decreased muscle tone.

Some organizations include hypotonic CP as an additional type (Goldsmith et al., 2016), though a commonly cited consensus definition excludes children with hypotonia as the sole motor finding from the CP diagnosis (Cans et al., 2007).

Mixed Cerebral Palsy

The term *mixed CP* is used when more than one type of motor pattern is present and when one pattern does not clearly predominate over another. The term *total body CP* is sometimes used to emphasize that certain types of CP (dyskinetic, ataxic, mixed, and spastic quadriplegia) involve the entire musculoskeletal system, whereas other forms of spastic CP (e.g., diplegia and hemiplegia) are localized to a particular region of the body.

Although there is some clinical utility in classifying CP on the basis of neuromotor characteristics (e.g., spasticity or dyskinesias), there tends to be a great deal of functional variability within specific subtypes. For example, some children with spastic diplegia may be able to walk independently, whereas others depend on a wheelchair for mobility. As described previously, tools such as the GMFCS have been useful in predicting functional outcomes.

ESTABLISHING THE ETIOLOGY OF CEREBRAL PALSY

In CP, the evaluation for the etiology is often done in parallel with the assessment that establishes the disability or functional diagnosis (Ashwal et al., 2004; National Guideline Alliance, 2017). Establishing the underlying etiology can have important implications for designing treatment and for understanding prognosis and recurrence risk in future children. It also can impact the parental feelings of guilt and responsibility. Information from the medical history and physical examination of a child is critical in establishing an etiology. For example, knowing that a child was born prematurely and has signs of spastic diplegia strongly suggests cerebral white matter injury. Similarly,

dystonic CP in the presence of a normal birth history may be associated with a neurogenetic or metabolic disorder (see Chapter 16).

With regard to specialized diagnostic testing, brain imaging is especially helpful (Accardo, Kammann, & Hoon, 2004; Ancel et al., 2006). Seventy to ninety percent of children with CP will have significant diagnostic findings on neuroimaging (Korzeniewski, Birbeck, DeLano, Potchen, & Paneth, 2007). Cranial ultrasound, an inexpensive, noninvasive imaging modality, has utility both in diagnosis and management of the high-risk neonate. Ultrasonography is used for fetal and neonatal screening; it can distinguish large malformations of the brain from abnormalities related to brain hemorrhage or injury (i.e., IVH, PVL).

Brain anatomic MRI is the most helpful imaging technique for establishing the cause of CP (Vermeulen, Wilke, Horber, & Krägeloh-Mann, 2010). Based on an understanding of normal brain development, careful interpretation of MRI studies can show patterns of selective vulnerability in brain structures characteristic of the nature of the insult, gestational timing, and severity (Barkovich, 2005). It should be noted that even a normal MRI can be of benefit, as it may lead to consideration of a potentially treatable metabolic disorder, such as dopa-responsive dystonia (Mink, 2003). Use of advanced MRI techniques such as diffusion weighted imaging, DTI, MR spectroscopy, and functional MRI (see Chapter 8) can provide additional information about brain metabolic function and white matter tract integrity/maturity. Evidence for clinical use of advanced methods (particularly for diffusion MRI) is emerging, but the technical complexity of analysis and interpretation continues to limit widespread routine use (George et al., 2017).

ASSOCIATED IMPAIRMENTS IN CEREBRAL PALSY

Many children with CP have associated impairments. The most common are intellectual disability, visual impairments, hearing impairments, speech-language disorders, seizures, feeding and growth impairments, and behavior-emotional disorders.

Assessment of intellectual functioning in children with CP may be difficult because most tests of cognition require responses that are dependent upon both oromotor and visual-motor skills. Even taking these limitations into account, approximately one half of children with CP have intellectual disability, and many of those with typical intelligence exhibit some degree of learning disability (Nordmark, Hägglund, & Lagergren, 2001). Children with the more severe types of CP are at a greater risk for more significant intellectual disability.

Visual impairments are common and diverse in children with CP. They may be both ocular (e.g., strabismus) and central (i.e., cortical visual impairment; Guzzetta, Mercuri, & Cioni, 2001; see Chapter 25). The premature infant may have severe visual impairment caused by retinopathy of prematurity. Nystagmus, or involuntary oscillating eye movements, may be present in the child with ataxia. Children with hemiplegia may present with homonymous hemianopia, a condition causing loss of one part of the visual field (Jacobson, Rydberg, Eliasson, Kits, & Flodmark, 2010). Strabismus is seen in many children with CP. Finally, children with CP are more prone to hyperopia (farsightedness) than typically developing children (Sobrado, Suarez, & Garcia-Sanchez, 1999).

Hearing, speech, and language impairments are also common, occurring in about 30% of children with CP. Children with CP caused by congenital cytomegalovirus or other intrauterine viral infections often have hearing loss (see Chapter 26). Dyskinetic CP resulting from basal ganglia/thalamus injury is associated with articulation problems because these structures influence tongue and vocal cord movement. In children with CP and typical cognitive development, expressive or receptive language disorders may be present and may evolve into a specific reading disability (see Chapter 20).

Approximately 40% of children with CP develop seizures (Nordmark et al., 2001). Children with more severe intellectual and physical disability are more prone to generalized seizures (Carlsson, Hagberg, & Olsson, 2003). Children whose CP is a consequence of brain malformation, infection, or severe gray matter injury are also at greater risk for generalized seizures (see Chapter 22).

Feeding and growth difficulties also are often present (Samson-Fang et al., 2002). They may be secondary to a variety of problems, including hypotonia, weak suck, poor coordination of the swallowing mechanism, tonic bite reflex, hyperactive gag reflex, and exaggerated tongue thrust. These problems may lead to poor nutrition and, in some cases, require the use of alternative feeding methods, such as tube feeding (see Chapter 29). Medical problems related to poor gastrointestinal motility (including gastroesophageal reflux and constipation) may add to these difficulties.

The combination of poor nutrition and lack of weight-bearing activities also leads to osteopenia (weak bones related to reduced bone mineral density). This places children with CP at increased risk for fractures. Bisphosphonates, which have been used to treat osteoporosis in older adults, have also been shown to be effective in treating osteopenia in CP (Hough, Boyd, & Keating, 2010).

As in other neurodevelopmental disabilities, individuals with CP are affected with psychiatric comorbidities at a rate that is higher than the general population. These include conditions such as anxiety, depression, and adjustment disorders. They also are more likely to have sleep disorders, such as obstructive sleep apnea. In addition, due to their primary condition, they are affected by pain, and thus pain management must be addressed adequately at each health care encounter (Fehlings, 2017).

These associated disorders contribute significantly to the issue of quality of life in individuals with CP (Liptak & Accardo, 2004; Samson-Fang et al., 2002). A comprehensive health plan implemented in the context of a well-defined medical home is a critical component to ensuring that the health needs of children with CP are adequately addressed (Cooley & American Academy of Pediatrics Committee on Children with Disabilities, 2004; see Chapter 41).

COMPREHENSIVE MANAGEMENT FOR INDIVIDUALS WITH CEREBRAL PALSY

Neuroplasticity

A key starting point for discussing management of CP is based on an understanding of neuroplasticity. **Neuroplasticity** refers to the ability of the central nervous system to change in response to environmental stimulation (Wittenberg, 2009). It is characterized by the inherently dynamic biological capacity of the CNS to undergo maturation, change structurally and functionally in response to experience, and adapt following injury (Ismail, Fatemi, & Johnston, 2017). The human brain grows rapidly from conception through early childhood. During this time, typical developmental changes include widespread creation and then destruction of interneuronal connections, or synapses. Experience-dependent and -expectant patterns of synaptic creation and pruning are one major postulated mechanism of early developmental neuroplasticity (Ismail et al., 2017). Neuron- and synapse-level plasticity mechanisms may provide the ability to adapt to environmental changes, to store information in memory (associated with learning), and to recover from brain and spinal cord injury (Johnston, 2009). There is a great deal of information in adults, especially following stroke, supporting the efficacy of neurorehabilitation directed at the plasticity (see Chapter 32).

The child's brain has greater plasticity than the adult brain (Cramer et al., 2011). In CP, as well as in other childhood neurodevelopmental disabilities, the overarching question concerning plasticity involves

the nature of the relationship between amount and timing of intervention and resultant outcome (Delgado et al., 2010; Vargus-Adams, 2009).

Overview of Management

Comprehensive management for children with CP includes both accurate diagnosis and effective treatment strategies. Management is based upon the recognition that each child requires a unique combination of medical and rehabilitative interventions that are developed through a team approach and tailored to the family structure and goals. Specialists in orthopedics, neurosurgery, genetics, ophthalmology, gastroenterology, neurology, physical medicine and rehabilitation, psychiatry, and neurodevelopmental pediatrics are all integral to developing a comprehensive medical-surgical treatment plan. Physical and occupational therapists, speech-language pathologists, audiologists, clinical and behavioral psychologists, special education consultants, and social workers are critical team members in developing the rehabilitation and educational plan. An interdisciplinary setting is the ideal approach to management of the child with CP.

It is very important that clinicians and families agree upon specific treatments as well as overall management goals. Typical goals include improvements in function, communication, ease of care, and pain management. Including the child in the decision-making process to the greatest extent possible is critical to successful plan implementation. Treatment should be integrated into the individual families' lifestyles, including other activities and commitments. An important practical consideration is the recognition that a specific medical treatment or therapy may be embraced by one family but rejected by another, even when the overall clinical findings are similar. In the management of CP, effective care coordination and the provision of a medical home are paramount (Figure 21.14).

Principles of Management

Management may be divided into rehabilitative, medical, and surgical components (Papavasiliou, 2009). Rehabilitative interventions include conventional therapeutic approaches (physical therapy and occupational therapy), serial casting, orthotic bracing, strength training, aquatherapy, hippotherapy (therapeutic horseback riding), and technology systems such as augmentative communication and power mobility. The focus in physiotherapy has shifted from traditional physical and occupational therapy to approaches combining

A family-centered medical home is *not* a building, house, hospital, or home health care service, but rather an approach to providing comprehensive primary care.

In a family-centered medical home the pediatric care team works in partnership with a child and a child's family to assure that all of the medical and nonmedical needs of the child are met.

Through this partnership the pediatric care team can help the family and child access, coordinate, and understand specialty care, educational services, out-of-home care, family support, and other public and private community services that are important for the overall health of the child and family.

The American Academy of Pediatrics (AAP) developed the medical home model for delivering primary care that is accessible, continuous, comprehensive, family-centered, coordinated, compassionate, and culturally effective to *all* children and youth, including those with special health care needs.

Figure 21.14. What is a family-centered medical home? (From National Center for Medical Home Implementation, American Academy of Pediatrics. [n.d.]. *What is a family-centered medical home?* Elk Grove Village, IL: Author. Retrieved from <http://medicalhomeinfo.org>; reprinted by permission.)

principles of motor learning and strength and fitness training. In addition to these physical approaches, specialists in social work and psychology who are aware of the effects of motor disability on other aspects of childhood development are of great benefit in fostering social/emotional growth and active participation of the child in the rehabilitation efforts.

In terms of medication, the most commonly used drugs for spasticity and rigidity include baclofen, diazepam, and botulinum toxin (see Appendix C). Carbidopa-levodopa and trihexyphenidyl have been found to be helpful for some children with dystonic CP. Tetrabenazine has been used successfully in selected patients with dyskinetic CP. The purpose of all these medications is to improve motor tone, which enables more physical activity or lessens pain. Orthopedic surgical interventions include tenotomies, tendon transfers, and osteotomies (see Chapter 9). Neurosurgical procedures, including intrathecal baclofen, selective dorsal rhizotomy (SDR), and deep brain stimulation (DBS), may be of benefit in carefully selected patients (Lynn, Turner, & Chambers, 2009).

Early Intervention and Education

A number of studies and reviews support the importance of CP-specific early intervention in optimizing neuroplasticity and reducing deleterious musculoskeletal outcomes. The emergence of earlier, more accurate

diagnostic assessment tools (e.g., MRI, Prechtl Qualitative Assessment of General Movements, the Hammett Infant Neurological Examination) has allowed identification of high-risk infants in some cases even before 5 months of age (Novak et al., 2017). Task-specific motor training early interventions, which focus on targeting use of the lower-functioning hand in constraint-induced therapy, maximize functional gains and are the new paradigm of care. Beginning therapy as soon as high-risk features are noticed in infants and young children with developmental delay has been a long-standing belief of families and professionals alike, and there is now a growing body of evidence supporting the principles and long-term benefits of early intervention (Novak et al., 2017). One approach would be daily in-home interventions with active parental involvement using activities that are fun and motivational with therapist support (Herskind, Griesen, & Nielsen, 2015). Despite the current focus on early intervention, it should be emphasized to families that no rigid critical period has been identified in broad domains of human development and that experience-dependent (and indeed experience-expectant) plasticity appears to continue through adulthood (Bruer, 2011). Early intervention as currently available should not be seen as a cure, and submaximal early intervention should not be seen as a reason to lose hope.

For most children with CP, the process of rehabilitation begins in the home environment under the Infant and Toddlers program within the Individuals with Disabilities Education Improvement Act of 2004 (IDEA; see Chapter 31), which emphasizes the involvement of parents so that they can learn effective methods of working with their child. Programs are individualized according to the specific needs of the child and the family. While emphasizing home-based services, these programs may also provide consultative and center-based interventions (see Chapter 31).

For many children with CP, entry into preschool represents the first major step into the wider community. Difficulties in accommodating the physical, nutritional, and medical needs of these children must be addressed. For school-age children, although concerns regarding motor function and medical needs continue, an increased attention is focused on learning disabilities, attention and behavior difficulties, intellectual disability, and sensory impairments. For many children, these associated conditions, rather than the motor disability, place them at greatest disadvantage relative to their typically developing peers. Children with CP have traditionally been segregated into classrooms with designations such as “multiply disabled” and “orthopedically impaired,” sometimes without proper regard for their intellectual needs. Inclusion is mandated by

federal law (IDEA) in general education classrooms and in the least restrictive environment. Inclusive environments, however, require significant collaboration between the general and special education models and work best when a team of educators and paraprofessionals is associated with each classroom (see Chapter 33).

Specific Rehabilitative Techniques

For children with CP, therapy may come in many different forms. Most children receive traditional forms of physical, occupational, and speech therapy. The most common method of motor therapy for the young child is neurodevelopmental therapy (NDT), an approach that is employed by both occupational and physical therapists. It is designed to provide the child with sensorimotor experiences that enhance the development of more typical movement patterns (Campbell, Palisano, & Orlin, 2012; see Chapter 32). NDT is an individualized program of positioning, therapeutic handling, and play, and goals include the normalization of tone and improved control of movement during functional activities.

A promising technique known as constraint-induced therapy, or forced-use therapy, has been introduced to help children with hemiplegic CP (Taub, Ramey, DeLuca, & Echols, 2004; Willis, Morello, Davie, Rice, & Bennett, 2002). The technique involves constraining the more functional arm or hand to force use of the less functional upper extremity. Randomized controlled trials suggest that this technique may be of significant benefit over traditional therapy alone in the short run (Aarts, Jongerius, Geerdink, van Limbeek, & Geurts, 2010). Early initiation of constraint-induced therapy after stroke shows benefit at 12 months, and persistent improvements in motor function are evident as late as 24 months after initial implementation, even if therapy is started over 1 year after the initial insult (Wolf et al., 2010).

Physical exercise is important to strengthen muscles and bones, enhance motor skills, and prevent contractures. In addition, the social and recreational aspects of organized physical activities can be highly beneficial (see Chapter 33). Many popular activities, including swimming, dancing, and horseback riding, can be modified so that children with CP can participate (Meregillano, 2004).

The Special Olympics, founded by Eunice Kennedy Shriver in 1968, has enabled thousands of children and young adults with intellectual disabilities and CP to take part in various sporting events. The rewards of engaging in competitive sports are invaluable for enhancing self-esteem and providing a sense of belonging to a peer group. Parents and professionals should encourage all children to participate in

whatever physical activities their interests, motivation, and capabilities allow.

Bracing, Splinting, and Positioning

Therapists make frequent use of braces and splints (collectively referred to as **orthotic** devices) and positioning (seating) devices as aids in the pursuit of functional goals for children with CP. These devices are employed to maintain adequate range of motion, prevent contractures at specific joints, provide stability, and control involuntary movements that interfere with function. For the legs, one of the most commonly prescribed orthotics is a leg brace known as an **ankle-foot orthosis** (AFO). The AFO stabilizes the position of the foot and provides a consistent stretch to the Achilles tendon (see Chapter 32).

A variety of splints can be used to improve hand function. For example, the resting hand splint is commonly used to hold the thumb in an **abducted** (away from the midline) position and the wrist in a neutral or slightly extended position. This helps the child to keep his or her hand open and works to prevent the development of hand deformities. Trunk and body bracing, called a body splint, is made of a flexible, porous material. It controls abnormal tone and involuntary movements by stabilizing the trunk and limbs. Most pediatric braces and splints are custom-made from plastics that are molded directly on the child, and so they must be monitored closely and modified as the child grows or changes abilities.

Positioning devices are used to promote skeletal alignment, to compensate for atypical postures, or to prepare the child for independent mobility. Proper positioning geared toward the age and functional status of the child is often a key intervention in addressing the tone and movement impairments associated with CP. For children who must sit for extended periods of time or who use a wheelchair for mobility, a carefully designed seating system becomes an all-important component of their rehabilitation. Careful attention to functional seating may also have long-term benefits in the prevention of contractures and joint deformities resulting from spasticity (Myhr, von Wendt, Norrlin, & Radell, 1995).

Adaptive Equipment

A wide variety of devices are available to aid mobility. For children who are ambulatory, the use of crutches, walkers, and canes can help in the attainment of walking or in improvement of the quality and range of ambulation. The forearm, or Lofstrand, crutch is used in preference to the familiar under-the-arm crutch. A posterior walker with wheels (i.e., the child is positioned in

front of the walker rather than behind) is used in preference to a standard forward-position walker without wheels. Canes are used less commonly.

For children with limited walking skills, wheelchairs are essential for maximizing mobility and function. A wheelchair with a solid seat and back is usually recommended. Some children, however, have difficulty using this type of chair unless modifications are made. The addition of head and trunk supports or a tray may be needed for the child who lacks postural control due to abnormalities in tone. The child with limited head control, feeding difficulties, or low tone may benefit from a high-backed chair that can be tilted back 10–15 degrees (Figure 21.15A). This helps to maintain the child's body and head in proper alignment, and it may help to prevent scoliosis. Special seating cushions or custom-molded inserts that conform to the contours of the body can offer necessary support for the child with orthopedic deformities such as scoliosis.

Motorized (power) wheelchairs can enhance the independence of children who are able to use them. They may be manipulated by hand control, head control, or mouth mechanisms for controlling both speed and direction (Figure 21.15B). These wheelchairs can include leg elevation and tilt-in-space options. They can provide increased independence for individuals who would otherwise be dependent upon others for pressure relief, self-positioning, and lower extremity stretching.

Special supportive strollers are an alternative to wheelchairs for mobility within the community or for the young child whose potential for ambulation has yet to be determined. These are lightweight and collapsible, yet they support the back and keep the hips properly aligned (Figure 21.15C).

Car seats are essential to the safety of all children who ride in automobiles. Several manufacturers offer adapted car seats that meet federal safety guidelines as well as provide proper support for the child with CP.

Figure 21.15. Three types of wheelchairs. A) High-backed, tilting chair with lateral inserts and head supports; B) motorized wheelchair with joystick control; and C) supportive collapsible stroller.

Often these models include a base that allows the seat to be used as a stroller or a positioning chair outside of the car. Car beds and special straps are also available for children who have more severe disabilities or who require these special adaptations temporarily (e.g., following surgery).

Assistive Technology/Augmentative and Alternative Communication

Assistive Technology (AT) is an umbrella term describing use of external items to improve functioning for individuals with disabilities. Items or devices used can range from simple, low-technology systems (e.g., communication boards made of cardboard) to customized state-of-the-art computer systems or mechanical aids. **Augmentative and Alternative Communication (AAC)** is a subcategory of AT that provides methods of communication for individuals with impairments in spoken and/or written language. *Augmentative* refers to methods to supplement communication and *alternative* when the child has no speech.

AT devices are often an integral part of the rehabilitation plan for children with CP having complex communication needs (see Chapter 36). Although it is often true that the simplest intervention is the best, the computer is seen as the future of AT. Computers can be used to control the environment, provide a lifeline with the outside world, enable a person to work at home, facilitate artificial speech and sight, and provide entertainment. Recently, there has been a lot of enthusiasm for devices such as the tablets and smartphones for individuals with disabilities, chronic illness, and other impairments due to their relatively low cost and the ease and simplicity of their interfaces, graphics, and applications.

While the tablets and other mobile technologies have opened the doors of communication to individuals who have complex communication needs with measurable short-term benefits, the goals of participation in home, community, and school are more difficult to evaluate and quantify. With open collaboration of all people who are involved in the care of individuals with CP, technology development can proceed in sync with the immediate and broader needs of individuals with CP (McNaughton & Light, 2015).

Neurocognitive Prosthetics

There is an evolving interest in using technology to restore function, which can be attained through neuroprosthetics and neural control interfaces. Neuroprosthetics modulate neural function by directly using

implanted electrodes and other hardware in the central nervous system to restore injured special senses or movement (Serruya & Kahana, 2008). Neuroprosthetics currently in use include cochlear and auditory mid-brain implants for individuals with profound sensorineural hearing loss (see Chapter 26), and deep brain stimulation used in the management of involuntary movements in dyskinetic forms of CP (see the Neurosurgical Procedures section below).

In contrast, neural-control interfaces can either invasively or noninvasively connect the brain to a computer or machine. Examples of commercially available neural-control interfaces include NeuroSky and Emotiv, by which the users control a computer game with their own “brain waves” as mediated through an electroencephalograph. Other noninvasive techniques include transcranial magnetic stimulation and transcranial direct current stimulation. It is hoped that further advances in neurocognitive prosthetics will improve both communication and mobility for individuals with a wide range of disorders, including CP.

Managing Spasticity and Dystonia

Spasticity and dystonia represent important targets for intervention in CP. The primary goals are to improve function, to prevent or postpone the musculoskeletal complications attendant to these conditions, and to ease the care of the child with significant muscle tightness.

Different treatment modalities work at different levels of brain and spine circuitry (Figure 21.16). Interventions may be employed singly, sequentially, or simultaneously depending on the specific clinical circumstance. As dystonia is caused by disturbances in the extrapyramidal motor control system, pharmacological interventions primarily target the brain and spinal cord. By contrast, the mechanisms that generate spasticity may be affected from the brain to the muscle itself. Therefore, a wider variety of therapeutic modalities are available to modulate the effects of spasticity (see Box 21.1). A potential pitfall in treatment revolves around the relationship between impairment (spasticity or dystonia) and disability. For some children, it is possible to significantly reduce spasticity or dystonia without improving (and in some cases even worsening) functional outcome. Therefore, consultation with experienced professionals who are intimately familiar with a child’s particular pattern of skills and impairments is critical to the proper selection of specific interventions (see Box 21.2).

Casting Tone-reducing, or inhibitive, casts are used in some centers as an adjunct to more traditional

Figure 21.16. Levels of intervention for spasticity and dystonia. A) Inhibitive casting, physical therapy, exercise, and medications such as dantrolene directly affect tone at the muscle level. B) Nerve blocks, motor point blocks, and botulinum toxin work variously at the level of muscle and neuromuscular junction. C) Selective dorsal rhizotomy reduces spasticity by interrupting the sensory component of the stretch reflex arc. D) Medications such as baclofen reduce spasticity at the level of the spinal cord. E) Medications for spasticity, such as diazepam, and medications for dystonia work at the level of the brain. (From Pellegrino, L., & Dormans, J. P. [1998]. Definitions, etiology, and epidemiology of cerebral palsy. In J. P. Dormans & L. Pellegrino [Eds.], *Caring for children with cerebral palsy: A team approach* [p. 46]. Baltimore, MD: Paul H. Brookes Publishing Co., Inc.; adapted by permission.)

methods of managing spasticity (Law et al., 1991). The casts are made for arms or legs and can be either designed for use in immobilization or during weight-bearing activities. Benefits of inhibitive casting include improved gait and weight bearing, increased range of motion, and improved functional hand use. Casts position the limbs so that spastic muscles are in lengthened positions, being gently stretched. Serial application of casts (serial casting) can allow the therapist to increase range of motion gradually in the presence of contractures. After maximal range and position have been achieved, a cast is worn intermittently to maintain the improvement. Casting is now most often used in conjunction with other therapeutic modalities, especially following injection of **botulinum toxin**, sold under the brand name Botox (Glanzman, Kim, Swaminathan, & Beck, 2004; Kay, Rethlefsen, Fern-Buneo, Wren, & Skaggs, 2004; Wasiak, Hoare, & Wallen, 2004).

Nerve Blocks, Motor Point Blocks, and Botulinum Toxin

Several injectable agents are available that can be used to target spasticity in particular muscle groups. Certain chemical agents such as diluted alcohol or phenol, which denature muscle and nerve protein at the point of injection, can produce a decrease in muscle tone for months. A **motor point block** with these agents effectively interrupts the nerve supply at the entry site to a spastic muscle without compromising sensation. The main side effect of the procedure is localized pain that may persist for a few days after the injection. Inhibition of spasticity lasts for 4–6 months, and the procedure can be repeated after the initial effect has worn off. This temporary reduction of spasticity allows for more effective application of physical therapy to improve range of motion and function and to potentially postpone orthopedic surgery.

Injectable botulinum toxin was approved as an alternative to motor point blocks in 2000 and has largely supplanted alcohol and phenol (Jefferson, 2004; Mooney, Koman, & Smith, 2003; Morton, Hankinson, & Nicholson, 2004; Pidcock, 2004). Botulinum toxin is produced by the bacterium that causes botulism and is among the most potent neurotoxins known. It works by blocking the nerve-muscle junction. Small quantities can be safely injected directly into spastic muscles without significant spread of the toxin into the bloodstream. The injection results in weakening of the muscle and reduction of spasticity for 3–6 months (the antispasticity effects of the injections dissipate over time). Although botulinum toxin is used mainly to treat spasticity in muscles of the limbs and trunk, other uses have been developed, such as injection of the salivary glands to reduce drooling (Jongerius et al., 2004). Although clarification is still needed regarding the definition of clinical indications and outcomes (Hoare et al., 2010), the use of injectable botulinum toxin has become a mainstay in the management of spasticity in CP and has also found applications for specific types of dystonia (Gordon, 1999; Jefferson, 2004; Mooney et al., 2003). Side effects, including weakness and mild flu-like symptoms, are usually mild and transient. It should be noted, however, that there are very rare reports in which botulism-like clinical pictures, including death, have been reported (Jankovic & Brin, 1991).

Oral Medication A variety of orally administered medications have been used to improve muscle tone in children with spasticity and rigidity (Krach, 2001; Tilton, 2006; see Appendix C).

Several medications used in Parkinson's disease in adults, including carbidopa-levodopa (Sinemet) and

BOX 21.1 EVIDENCE-BASED PRACTICE**Spasticity Treatments**

Guidelines: American Academy of Neurology guidelines for spasticity (Delgado et al., 2010) and UK National Guideline Alliance guidelines for spasticity in under-19s (2012; updated without change in 2016)

Treatment	Local or general	Temporary, permanent, or reversible	Recommended settings and level of evidence (see text for detailed indications, contraindications, and considerations)
Oral medications			
Diazepam	General	Temporary	Short-term, as-needed treatment (Delgado et al., 2010) “Consider” for rapid effect, discomfort/pain, spasms, or functional disability (National Guideline Alliance, 2012) Green light (“Effective, do it”) rating (Novak et al., 2013)
Oral baclofen			“Consider” for sustained, long-term effect for discomfort/pain, spasms, or functional disability. “Consider” a trial if dystonia is considered to be contributing significantly to problems of posture, function, or pain (National Guideline Alliance, 2012) Overall insufficient data (Delgado et al., 2010) Yellow light (“Uncertain effect; measure outcomes for progress”) rating (Novak et al., 2013)
Tizanidine			Overall limited evidence (Delgado et al., 2010) Yellow light (“Uncertain effect; measure outcomes for progress”) rating (Novak et al., 2013)
Dantrolene			Overall insufficient data (Delgado et al., 2010) Yellow light (“Uncertain effect; measure outcomes for progress”) rating (Novak et al., 2013)
Trihexyphenidyl, Levodopa			“Consider” a trial if dystonia is considered to be contributing significantly to problems of posture, function, or pain (National Guideline Alliance, 2012)
Injectable medication			
Botulinum toxin type A	Local/segmental	Temporary	“Consider” in focal upper or lower extremity spasticity when impeding function, causing pain, disturbing sleep, interfering with other therapies, or for cosmetic purposes (National Guideline Alliance, 2012) Effective and generally safe (Delgado, 2010; Esquenazi et al., 2013) Green light (“Effective, do it”) rating (Novak et al., 2013)
Phenol, alcohol, or botulinum toxin type B			Insufficient data (Delgado et al., 2010) Yellow light (“Uncertain effect; measure outcomes for progress”) rating (Novak et al., 2013) (alcohol and phenol)
Therapy-based interventions			
Serial casting	Local/segmental	-	Ankles: Green light (“Effective, do it”) rating Elsewhere: Yellow light (“Uncertain effect; measure outcomes for progress”) rating (Novak et al., 2013)
Orthotics (e.g., AFOs)	Local/segmental	-	Yellow light (“Uncertain effect; measure outcomes for progress”) rating (Novak et al., 2013)
Hip bracing	Local/segmental	-	Red light (“Ineffective, don’t do it”) rating (Novak et al., 2013)

Constraint-induced movement therapy, bimanual training, context-focused therapy, goal-directed/functional training, occupational therapy following botulin toxin injection, home programs for improving motor activity performance and/or self-care	Local/ segmental	-	Green light (“Effective, do it”) rating (Novak et al., 2013)
Craniosacral therapy, neurodevelopmental therapy, sensory integration			Red light (“Ineffective, don’t do it”) rating (Novak et al., 2013)
Invasive interventions			
Intrathecal baclofen pump	General	Reversible	“Consider” if persistent difficulties with pain/spasms, posture, function, or ease of care despite noninvasive treatments (National Guideline Alliance, 2012) Yellow light (“Uncertain effect; measure outcomes for progress”) rating (Novak et al., 2013)
Orthopedic surgery	Local/ segmental	Permanent	“Consider” as an adjunct if concerns regarding hip displacement or spinal deformity to prevent deterioration and improve function (National Guideline Alliance, 2012)
Selective dorsal rhizotomy	Local/ segmental	Permanent	“Consider” to improve walking in young people with spasticity and GMFCS II or III (National Guideline Alliance, 2012) Green light (“Effective, do it”) rating (Novak et al., 2013)

BOX 21.2 INTERDISCIPLINARY CARE

The Role of the Physical Therapist

In the team approach of caring for children with cerebral palsy (CP), the role of the physical therapist (PT) includes performing a full examination of every body system related to the control of movement, seating/positioning, and mobility. For children with CP, this examination may have a different focus for infants, school-age children, teens, and adults. Routine musculoskeletal examination with specialized examination methods may be applied to determine needs for seating, positioning, gait or standing assistive devices, bracing, and mobility systems such as wheelchairs. The PT’s assessment leads to establishing a plan of care with achievable goals.

Common goals of the physical therapist in management of the child with CP

Examination	Assessment	Treatment
Determining the presence and severity of gross motor delays	Determining a prognosis as it relates to movement, positioning, and mobility	Prescribing bracing, seating or mobility equipment, and adaptive equipment
Determining if movement patterns are typical or impaired	Infants and toddlers: Providing direct services, treatment, and consultation/education	Providing consultative services to child/family, medical team, or program
Contributing to classification (e.g., Gross Motor Function Classification System—Expanded and Revised (GMFCS–E&R; Palisano, Cameron, Rosenbaum, Walter, & Russell, 2006)	School PT: Helping the child gain access to education and social development in school and contributing to the individualized education program (IEP)	Education: Training parents, family, caregivers, and assistants in performing home programs or in implementing aspects of IEP
Screening: Identifying risks, need for preventive intervention, or need for referral to other providers	In some medical settings, the PT consults both the child and the medical team	Prevention: Identifying risk for developing secondary complications of CP and intervening to prevent or manage complications or reduce risk
Monitoring change over time or in response to an intervention		Discharge planning: Determining need for ongoing PT, monitoring needs, and referring to other necessary services or providers

trihexyphenidyl (Artane), have been found to be beneficial for some children with dyskinetic forms of CP (Mink & Zinner, 2009).

Although some specialists prefer trihexyphenidyl, others have reported benefits with levodopa. The medications most commonly used to control spasticity and rigidity are diazepam, baclofen, and dantrolene. Diazepam and its derivative compounds, lorazepam and clonazepam, affect brain control of muscle tone, beginning within 30 minutes after ingestion and lasting about 4 hours. Withdrawal of these drugs should be gradual as physical dependency can develop. Side effects include drowsiness and excessive drooling, which may interfere with feeding and speech. As a result of these side effects, they are less commonly used than oral baclofen.

Baclofen, a GABA B-receptor agonist, was initially used to treat adults with multiple sclerosis and traumatic damage to the spinal cord. It is now commonly used in CP clinics around the world. In children with CP, the most common side effects of the oral form of the medication are drowsiness, nausea, headache, and low blood pressure. About 10% of children treated with baclofen experience side effects that are unpleasant enough to necessitate discontinuation of the medication. Care must be taken when stopping the medication to gradually taper it, as rapid withdrawal can lead to severe side effects, including hallucinations.

Dantrolene works on muscle cells directly, as a calcium channel blocker, to inhibit their contraction. Side effects include drowsiness, muscle weakness, and increased drooling. A rare adverse effect of this drug is severe liver damage, so liver function tests should be performed periodically. Because of this side effect, this medication is used with decreasing frequency.

Although a discussion of the range of side effects associated with oral medications is beyond the scope of this chapter, several generalizations can be made. For example, some medications have easily recognizable side effects, such as sedation from diazepam and seizures from acute baclofen withdrawal. Others may be more subtle, such as cognitive or personality changes with trihexyphenidyl (Carranza-del Rio, Clegg, Moore, & Delgado, 2011).

Periodic drug “holidays” should be considered to determine whether benefits are persistent. As always, clinicians should listen carefully to parental or caregiver concerns about any changes in their children after medication initiation.

Neurosurgical Procedures Intrathecal baclofen is a therapeutic modality that allows for the direct delivery of baclofen into the spinal fluid (i.e., intrathecal)

space, where it can inhibit motor nerve conduction at the level of the spinal cord (Disabato & Ritchie, 2003; Fitzgerald, Tsegaye, & Vloeberghs, 2004; Tilton, 2004). A disk-shaped pump is placed under the skin of the abdomen, and a catheter is tunneled below the skin around to the back, where it is inserted through the lumbar spine into the intrathecal space. Baclofen is stored in a reservoir in the disk that can be refilled, and the medication is delivered at a continuous rate that is computer controlled and adjustable. Because the drug is delivered directly to its site of action (the cerebrospinal fluid), a much lower dosage can be used, with a resultant reduced risk of side effects. Improvements in ease of care and comfort are commonly reported. Although functional gains in lower extremity, upper extremity, and even oral/motor function have been observed (Fitzgerald et al., 2004), clear improvements in ambulatory individuals has not been demonstrated (Pin, McCartney, Lewis, & Waugh, 2011). The main disadvantages of intrathecal baclofen are hypotonia (low muscle tone), increased seizures in individuals with known epilepsy, sleepiness, and nausea/vomiting (Gilmartin et al., 2000). Complications related to mechanical failures and infection and the need for intensive and reliable medical follow-up are also significant considerations (Murphy, Irwin, & Hoff, 2002).

Selective dorsal rhizotomy (SDR) is a procedure that reduces spasticity by interrupting the sensory component of the deep tendon reflex, which is exaggerated in children with spastic forms of CP. The surgery reduces spasticity permanently in the legs but not in the arms, so its use is confined mainly to children with spastic diplegia who have good antigravity strength. Although uncertainty exists in regard to long-term functional outcomes in children who undergo this procedure (Koman et al., 2004; Tedroff, Löwing, Jacobson, & Åström, 2011), other recent reports have been more encouraging in this regard (Engsberg, Ross, Collins, & Park, 2006; Langerak et al., 2009).

Deep brain stimulation (DBS) is a neurosurgical procedure involving the implantation of a neurostimulator and electrodes that send electrical impulses into brain structures, including the basal ganglia. The impulses are calibrated by an experienced neurologist or technician. While effects are directly mediated by electrical axonal stimulation, there may be additional secondary effects on synaptic plasticity (Herrington, Cheng, & Eskandar, 2016). With careful patient selection, DBS is a promising intervention for children with dyskinetic CP, although improvements are more dramatic in children with genetic forms of dystonia (such as those with DYT1 mutations; Air, Ostrem, Sanger, & Starr, 2011; Elia et al., 2018; Fehlings et al., 2018).

Orthopedic Procedures

Because of the abnormal or asymmetrical distribution of muscle tone, children with CP are susceptible to the development of joint deformities. The most common of these result from permanent shortening or contracture of one or more groups of muscles around a joint, which limits joint mobility. Orthopedic surgery is done to increase the range of motion by lengthening a tendon, cutting through muscle or tendon (release), or moving the point of attachment of a tendon on bone. For example, a partial release or transfer of hyperactive hip adductor muscles (which cause scissoring of the legs) may improve the child's ability to sit and walk and may lessen the chances of a hip dislocation (Hägglund et al., 2005; Stott, Piedrahita, & American Academy for Cerebral Palsy and Developmental Medicine, 2004). A partial hamstring release, involving the lengthening or transfer of muscles around the knee, also may facilitate sitting and walking. A lengthening of the Achilles tendon at the ankle improves toe walking (Figure 21.17).

More complicated orthopedic procedures may be required for correction of a dislocated hip. If this is diagnosed when there is a partial dislocation (called subluxation), release of the hip adductor muscles alone can be effective (Figure 21.18). If the head of the femur (the thigh bone) is dislocated more than one third to one half of the way out of a hip joint socket, a more complex procedure called a varus derotational osteotomy may be necessary. In this operation, the angle of the femur is changed surgically to place the head of the femur back into the hip socket (Figure 21.19). In some cases, the hip socket also must be reshaped to ensure that the hip joint remains functional. Sometimes muscle releases or lengthening are performed at the same time as these procedures.

For ambulatory children with CP, deciding which type of surgery is most likely to improve function is a

Figure 21.17. Achilles tendon lengthening operation. When the heel cord is tight, the child walks on his or her toes. Surgery lengthens the heel cord and permits a more flat-footed gait.

Figure 21.18. Adductor tenotomy. This operation is done to improve scissoring (Figure 24.11) and to prevent hip dislocation caused by contractures of the adductor muscles in the thigh. A) In this procedure, the iliopsoas, adductor brevis, and adductor longus muscles are cut, leaving the adductor magnus intact. B) The child is then placed in a cast for 6–8 weeks to maintain a more open (abducted) position. C) The muscles eventually grow together in a lengthened position, allowing improved sitting and/or walking.

complex issue. Computerized gait analysis conducted prior to surgical intervention has become increasingly common as an aid in the decision-making process. Precise measurements obtained through motion analysis, force plates, and electromyography offer detailed information relating to specific abnormalities at each lower extremity joint as well as the muscle activity that controls motion through all phases of the gait (Cook, Schneider, Hazlewood, Hillman, & Robb, 2003). Preoperative gait analysis helps to determine exactly which procedures are likely to be successful. Postoperative analysis can provide an objective measure of outcome.

Scoliosis: Conventional Rods vs. Magnetic Controlled Growing Rods

In addition to treating contractures and dislocations, orthopedic surgeons are involved in the treatment of scoliosis (progressive curvature of the spine). Treatment of significant scoliosis

Figure 21.19. Dislocation of the hip. The upper x-rays (frontal view) show a normal hip (left x-ray) and a hip dislocated on both sides (right x-ray). The arrows indicate the points of dislocation. The lower pictures show the results of a varus derotational osteotomy to correct the left-hip dislocation. The femur has been cut and realigned so that it now fits into the hip socket. Pins, which are later removed, hold the bone in place until it heals.

ranges from a molded plastic jacket or a chair insert to surgery that straightens the spine as much as possible.

Children with CP are at increased risk of developing scoliosis, which can lead to medical complications including pulmonary and cardiac sequelae and difficulty with positioning, which can cause pain and secondary skin breakdown. The deformity can also affect the young person's self-esteem. For a number of years orthopedic surgical intervention has involved the placement of spinal rods with fusion of the vertebrae to straighten the spine (Figure 21.20). In the young child who is still growing, this approach requires repeated operations given linear growth over time.

Self-lengthening rods (magnetic controlled growing rods) have been developed for children under 10 years of age with severe spinal curves. These rods allow for vertical growth and correct the spinal deformity. Once placed, these rods can be lengthened noninvasively with an external magnetic device. However, even these rods are not permanent and require replacement as the child grows. As such, they are only

beneficial for children too young for spinal fusion. It should also be recognized that this is a new surgical technique—so a precise long term risk-benefit ratio has not yet been determined.

Complementary Health Approaches

When conventional approaches do not lead to the anticipated improvements, families may explore other treatment options, including complementary health approaches (often called complementary and alternative medicine; Oppenheim, 2009; see Chapter 39).

Complementary health approaches includes acupuncture, craniosacral therapy, myofascial release, therapeutic taping, diet and herbal remedies, electrical stimulation, chiropractic treatments, massage, and hyperbaric oxygen therapy. Although there are individual reports and testimonials of dramatic improvements with various alternative therapies, some carry significant risks. Furthermore, rigorous studies have not been conducted to assess efficacy. As with any

Figure 21.20. Treatment of scoliosis may require spinal fusion. This x-ray shows improved scoliosis following a Luque procedure. During this surgery, the position of the spine is improved using metal hooks, rods, and wires, while bone graft material fuses the spine in position.

treatment, families and clinicians should consider cost, efficacy, and potential side effects before embarking on one of these approaches.

Transition into Adulthood

Adolescence is a critical time in life for all individuals, but for teenagers with CP there are additional challenges (Wood, Kantor, Edwards, & James, 2008). There is the need to transition from pediatric health care providers to those who manage CP in adults, and there are job training, employment, social, recreation, housing, and insurance considerations that require careful planning (see Chapter 40).

Adult Outcomes

Adults with CP are living longer and leading more independent lives than in the past as a result of new treatment options. However, they face challenges, including medical care, accessibility, and vocational opportunities (Tosi, Maher, Moore, Goldstein, & Aisen, 2009; Watson, Parr, Joyce, May, & Le Couteur, 2011).

Although medical care is well established for children with CP, it is more fragmented for adults (Turk, 2009). Adults with CP should look for practitioners

who are experienced in the care of chronic disorders and who can provide the additional time that may be required for evaluation. They also need to recognize the importance of preventive care and report any changes in neurological function, as this may represent new impairments secondary to the underlying motor disorder. Adults with CP identify pain as a significant problem and should be encouraged to seek medical care in this circumstance (Vogtle, 2009).

Mobility and the ability to perform activities of daily living should be carefully monitored because some adults experience slow declines over time. Individuals should be provided with instruction in practical matters, such as hiring quality personal aides and caregivers, as well as in self-advocacy and seeking employment opportunities when able.

Although most children with CP will live to adulthood, their projected life expectancy may be less than that of the general population (Hemming, Hutton, Colver, & Platt, 2005; Katz, 2003). For example, an individual with hemiplegic CP probably will have a typical life span, whereas a person with spastic quadriplegia may not live beyond age 40 because of respiratory and nutritional issues (Strauss & Shavelle, 2001). Children with very severe impairments, measured in terms of functional characteristics, have the poorest outcome. Children who cannot lift their heads and are fed via gastrostomy tube may not survive to adulthood (Strauss, Shavelle, & Anderson, 1998).

Excess mortality for people with CP may also be related to comorbid risks such as seizures and aspiration, as well as an increased risk for breast cancer, brain tumors, and circulatory and digestive diseases, most likely related to inadequate medical screening (Murphy, 2010). Unintentional injury rates (e.g., falls) for people with CP are also higher than in the general population (Cooley & American Academy of Pediatrics, 2004; Strauss, Cable, & Shavelle, 1999).

Motor skills and mobility may not be the primary determinant of societal independence; personal characteristics, health status, and environmental factors will also factor into an outcome (Liptak & Accardo, 2004). In fact, the ability to successfully participate in society may be more strongly related to intellectual and interpersonal strengths than to physical abilities. Although approximately one half of individuals with CP have typical intelligence, most still have difficulty leading completely typical lives. This may result from factors ranging from family support and quality of educational programs to availability of community-based training and technical support (Murphy, Molnar, & Lankasky, 1995; Russman & Gage, 1989). In one study of young adults with CP (van der Dussen, Nieuwstraten, Roebroek, & Stam, 2001), 53% of individuals had some

form of secondary education but only 36% subsequently engaged in paid employment. It is hoped that these figures will improve as a result of federal mandates (e.g., the Americans with Disabilities Act of 1990) that define the rights of people with disabilities and are gradually making inroads into societal perceptions of disability. Ultimately, strengthening support to families (Raina et al., 2005), providing ready access to quality medical care, improving special education services, increasing opportunities for employment, and changing attitudes about disabilities in society at large may do as much for children with CP as traditional therapeutic and medical interventions.

ADVOCACY AND AWARENESS

“Nothing about us without us” is a term that is widely utilized to express the belief that the stakeholders should be involved in the decisions that are made about them. In the disability world, this was elegantly expressed by James Charlton in his classic book, *Nothing About Us Without Us: Disability Oppression and Empowerment*, in which he discusses both the problems that people with disabilities face and the solutions in regard to self-determination (Charlton, 2000).

One of the most powerful means to promote self-determination is through social media, which is a collection of computer-mediated tools that promote communication through networks and virtual communities whereby people with similar interests can communicate with each other. It is a powerful way for individuals to share information about common interests. By facilitating communication, these networks can reduce feelings of isolation and provide a means for people to discuss sensitive problems with which only others with similar concerns can relate.

Benefits include a wide audience reach and real-time interactivity and immediacy. With the advent of easily accessible, web-based information on CP diagnosis, management, and care, individuals with CP and their families now have the ability to communicate more freely and participate more actively in medical and rehabilitative decision making and care. There are a number of sites that provide factual information of benefit in this regard. One good example of this is the web site Cerebral Palsy Foundation (<http://yourcpf.org/>), which provides fact sheets, expert commentaries, resources, videos, news, and blogs.

FUTURE DIRECTIONS

Although advances for individuals with CP never come as quickly as needed or wanted, the future offers hope

in a number of areas. These include opportunities for collaborative research, translating basic science into cutting-edge treatments, improved early diagnosis, and improved care in the transition from childhood to adulthood.

Cerebral Palsy Collaborative Research

One of the most encouraging developments is the ongoing work of the international collaboration of centers (“surveillance programs”) dedicated to the care of children with CP through the use of registers and surveillance. Currently there are nearly 40 surveillance programs worldwide (Goldsmith et al., 2016). The first large network established in 1998 was the Surveillance for Cerebral Palsy in Europe, now consisting of 24 centers in 20 countries, whose goals are to use epidemiologic data to monitor trends in care, to improve understanding of cause, to promote dissemination of knowledge, and to facilitate research (<http://www.scpenetwork.eu/en/cerebral-palsy/>). Other groups, including the Australian Cerebral Palsy Register (ACPR), utilize country-wide data to study epidemiology and causes as well as plan for current and future prevention and service provision needs (Australian Cerebral Palsy Register, 2016). In the United States, the Metropolitan Atlanta Developmental Disabilities Surveillance Program has been of great benefit in providing data on CP, as well as intellectual disability, hearing impairment, visual impairment, and autism spectrum disorder (Avchen, Bhasin, & Yeargin-Allsopp, 2006).

Similarly, national collaborative efforts to merge large multicenter data sets for future research will contribute to the advancement of knowledge, including better understanding of variations in clinical care and treatment effect for individuals with CP. The emerging CP Research Network (CPRN) is a new collaborative network of participating CP centers. A core project of CPRN is to develop a U.S.-based CP clinical registry to support future research questions and quality initiatives (CPRN, 2018). Overall, by looking at populations more than individuals, trends can be characterized and large data sets analyzed to create generalizable knowledge.

CP research has been limited in the past by small studies with lack of reproducible results. The recent publication of CP common data elements (CDEs) and outcome measures for children and young people with CP will standardize data collection and assessment. Routine use of these CP CDEs across clinical studies and clinical practice will increase data quality and data sharing, accelerate meta-analysis of studies and clinical trials across centers, and increase the generalizability of results and translation of evidence within

clinical practice (NINDS Common Data Elements, 2018; Schiariti et al., 2018).

There is exciting ongoing research targeting brain injury in the high-risk infant, both those that are born preterm and those born at term with HIE. Emerging information has shown that brain cooling for 3 days decreases the risk of death or severe disability in term infants with HIE by a variety of mechanisms, including reducing the metabolic demand of brain cells, reducing inflammation, and decreasing cell death. Current guidelines stop short of recommending widespread adoption of therapeutic hypothermia but focus on maintaining consistent comprehensive care when it is offered (Committee on Fetus and Newborn, 2014). In practice, the use of therapeutic hypothermia is guided by clinical judgment and the specifics of the clinical setting, especially the degree of encephalopathy and hypoxia. Erythropoietin, a cytokine with evidence of neuroprotection in animal models, is also being tested in both preterm and term high-risk infants (Rangarajan & Juul, 2014).

In addition, a promising new therapy for CP secondary to perinatal brain injury is nanomedicine-based treatment. Nanomaterials such as dendrimers, which are very small globular molecules, can provide a vehicle to deliver drugs directly to brain cells that are subject to neuroinflammation and injury. In this way, drugs such as N-acetyl cysteine can potentially be used to promote brain repair and regeneration, hopefully decreasing brain cell injury and enabling typical growth. Currently this is in the research realm and is not used to treat infants (Balakrishnan, Nance, Johnston, Kannan, & Kannan, 2013).

The introduction and now widespread use of advanced genetic testing, including chromosomal microarray and whole-exome sequencing, has provided families and providers etiologic information leading to better prevention, treatment, and family counseling (see Chapter 1). Some of these disorders act through specific genetic mechanisms, while others may predispose infants to acute perinatal events at the time of labor and delivery. Advanced knowledge in this regard can be of benefit in planning for delivery and future pregnancies.

Inborn errors of metabolism (IEMs) are individually rare but collectively common group of genetic diseases with abnormal metabolic pathways, leading to abnormal accumulation of substances and/or reduced ability to make essential compounds with presentations that often mimic CP (see Chapter 16). Effective treatment of IEMs can either be primary or improve function or stabilizing by preventing or slowing further brain injury (Leach, Shevell, Bowden, Stockler-Ipsiroglu, & van Karnebeek, 2014).

Bioengineering advances, especially in robotics, demonstrate promise toward improving function and mobility in children with CP. The field of pediatric neurorehabilitation has rapidly evolved with technological advancements in rehabilitation robotics and computer-assisted systems. For example, preliminary research shows that lower extremity robotic exoskeletons improve crouch gait and may help maintain mobility in children with CP as they age (Lerner, Damiano, & Bulea, 2016).

Advances in Clinical Care

A number of studies and reviews support the importance of CP-specific early intervention to neuroplasticity and prevention of deleterious musculoskeletal outcomes (Novak et al., 2017). Early interventions that focus on task-specific motor training (e.g., constraint-induced therapy) maximize functional gains and are the new paradigm of care. Beginning therapy for infants and young children with developmental delay has been a longstanding belief of families and professionals alike, and there is now a growing body of evidence supporting the principles and long-term benefits of early intervention (Novak et al., 2017). Emerging innovative approaches include tele-rehabilitative tools, combining home-based, goal-directed, task-specific interventions that are fun and motivational with remote monitoring and structuring by therapists and with active parental involvement (Sgandurra et al., 2017).

Opportunities for work, social, and community participation of individuals with disabilities including CP have increased as individuals and families have become self-empowered and more visibly engaged in society. From the professional's perspective, it is very important to "meet people where they are" and address their concerns with recommendations for care as a way to meet their goals. For the person with CP, a partnership with the professional is of tantamount importance to establish and promote goals and outcomes desired by the individual.

SUMMARY

- Cerebral palsy represents a group of chronic motor disorders that result from malformation or injury of the developing brain.
- The impairments associated with CP are variable and nonprogressive, but permanent. These impairments lead to varying degrees of disability that are related to functional mobility, daily living skills, and communication-socialization skills.

- Effective management requires an interdisciplinary strategy that seeks to maximize function and opportunity. Efforts founded on the principles that are articulated in federal legislation will create new opportunities for greater participation and enhanced quality of life for individuals with CP.
- New treatment modalities offer improved quality of life and educational opportunities. The challenge is to provide these opportunities in a changing medical environment, where a premium is not always placed on coordination of care.

CHAPTER 22

Epilepsy

Tesfaye Getaneh Zelleke, Dewi Frances T. Depositario-Cabacar,
and William Davis Gaillard

Upon completion of this chapter, the reader will

- Know the signs and symptoms of epilepsy
- Understand the epidemiology and causes of epilepsy
- Understand the basic classification of epilepsy
- Be familiar with common epilepsy syndromes
- Be knowledgeable about the evaluation and treatment of epilepsy
- Be aware of anti-seizure medications and their side effects

Seizures, also referred to as “fits” or “convulsions,” are transient disturbances of brain function resulting from an abnormally excessive excitation of cortical neurons. They are seen frequently in childhood. As many as 1 in 10 children will experience at least one seizure before adulthood (Hauser, 1994). The clinical signs and symptoms will vary depending on the location of the epileptic discharge in the cerebral cortex and the extent of spread of the discharge in the brain. Seizures can cause changes in motor movement (e.g., **tonic** [rigid] or **clonic** [uncontrolled jerking] movements), sensation (e.g., a tingling sensation), bodily function (e.g., incontinence), attention (e.g., loss of attention), awareness, and behavior (e.g., loss of consciousness or presence of unusual behaviors such as stereotypic actions).

Seizures can be provoked by an infection (e.g., meningitis or encephalitis), metabolic disturbance (e.g., hypoglycemia), a toxic agent (e.g., pesticides), trauma, or other acute illness. A fever (in children ages 6 months–6 years), an overdose of certain medications (e.g., insulin), meningitis, or a fall in which the

child hits his or her head can lead to a seizure (Huang, Chang, & Wang, 1998). Most seizures are either solitary and often provoked events (e.g., a single seizure following a minor head trauma) or limited to a specific and narrow age window (e.g., febrile convulsions).

By contrast, the diagnosis of epilepsy requires two unprovoked seizures that occur at least 24 hours apart. The prevalence of epilepsy in the general pediatric population is 4 to 10 per 1,000 (Berg, 1995). It has variable severity; an individual may experience anywhere from two or three seizures to hundreds over a lifetime. Epilepsy may have a clear origin (e.g., resulting from a malformation of cortical development or perinatal stroke), or it may not have an identifiable cause.

Children with developmental disabilities are at increased risk for epilepsy (Sunder, 1997). For example, it is five times more common in children with cerebral palsy than in typically developing children (Hundozi-Hysenaj & Boshnjaku-Dallku, 2008). With intellectual disability, the risk of developing epilepsy throughout one’s lifespan is 15%–20% (Besag, 2002; Forsgren,

Edvinsson, Blomquist, Hiejbel, & Sidenvall, 1990). In addition, if a child has comorbid conditions the risk for epilepsy is increased. For example, autism spectrum disorder (ASD) is associated with a 2% risk of manifesting epilepsy by 5 years of age and an 8% risk by 10 years (Tuchman & Rapin, 2002); however, this risk increases to 35% at 5 years and 67% by 10 years if the child has intellectual disability associated with ASD. In general, the more severe the pathology, the higher the risk of epilepsy (Holmes, 2002; Box 22.1).

The control of epilepsy in children with developmental disabilities tends to be harder to achieve, and medically refractory epilepsy (more than three seizures per year despite treatment with three standard anti-seizure medications [ASMs]) is more common (Airaksinen et al., 2000; Alvarez, Besag, & Iivanainen, 1998). Furthermore, both epilepsy and ASMs may contribute to learning difficulties and to disruptive behavior. Children with epilepsy exhibit a higher incidence of cognitive impairments, attention-deficit/hyperactivity disorder (ADHD), anxiety disorders, and depression.

■ ■ ■ CASE STUDY

Patricia is a 7-year-old girl who has been referred to the neurology clinic due to “spells.” She has been reported by her teachers at school to have staring spells and was thought to have difficulties with attention. Her teacher has noticed that she sometimes submits a written test with unfinished answers. There are also occasions when Patricia feels that she has missed a conversation and is often teased by her classmates. At the neurology clinic,

the pediatric neurologist had her hyperventilate by blowing a pinwheel; this elicited a typical spell. To confirm the clinical impression and establish a diagnosis, a sleep-deprived electroencephalogram (EEG) was done, which showed a generalized 3-Hz spike and wave pattern characteristic of absence seizures. Patricia was started on ethosuximide, but she continued to have seizures. Her medication dose was further increased, and she became asymptomatic. A follow-up EEG was normal. Her grades have also improved. She has been doing well for 2 years without any seizures, and the plan is now to discontinue her medication.

Thought Questions:

If a child is having “staring episodes” at school, what observations would help distinguish wandering attention from seizures? How might having epilepsy affect a child’s school attendance and performance?

EPILEPSY: DEFINITIONS AND CLASSIFICATION

Epilepsy, derived from the Greek word meaning to *take hold of or seize* (Reynolds, 2000), is a neurologic condition in which a person experiences recurrent unprovoked seizures (Hauser, Rich, Lee, Annegers, & Anderson, 1998). Epilepsy has always been defined as two unprovoked seizures occurring more than 24 hours apart. In 2014, a task force expanded this definition by proposing that epilepsy may be defined by any of the following

BOX 22.1 EVIDENCE-BASED PRACTICE

Epilepsy, Autism Spectrum Disorder, and Behavior

Children with autism spectrum disorder (ASD) have an increased incidence of epilepsy (10%–30%; Tuchman, 2013), which is especially prevalent among children who also have concomitant intellectual disability (ID). In addition, children with ASD have an increased incidence of abnormalities on EEG, even in the absence of clinical seizures (20%–30%; Spence & Schneider, 2009). Compared with typically developing children, children with ASD also have increased difficulties with impulsivity, hyperactivity, agitation, mood instability, self-injury, and aggression. A possible link between epilepsy in autism and increased difficulties with behavior has long been a subject of speculation based on the idea that changes in brain function related to seizures might lead to worsening behavior in children with ASD. However, a cross-sectional study involving 2,645 children with ASD found that when controlled for ID, there was no difference in maladaptive behaviors between children with and without epilepsy. In other words, the presence of maladaptive behaviors was most strongly correlated with lower cognitive ability, rather than with epilepsy. The one exception was hyperactivity, which did appear to be increased in the epilepsy group, independent of cognitive level (Viscidi et al., 2014).

The relationship between developmental disabilities such as autism and ID and epilepsy is complex. Future research will help to clarify the nuances of this relationship.

criteria: 1) at least two unprovoked (or reflex) seizures occurring more than 24 hours apart; 2) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; or 3) diagnosis of an epilepsy syndrome (see discussion below; Fisher et al., 2014). Unprovoked seizures are seizures that occur spontaneously, without an obvious inciting event (such as a high fever or drug/alcohol withdrawal). Reflex seizures are provoked by specific sensory stimuli (such as flashing lights) or specific movements or activities in specific individuals, and they occur in certain types of epilepsy. The incidence of epilepsy ranges from 41 to 187 out of 100,000 and is highest in the first year of life (Camfield & Camfield, 2015). After a single unprovoked seizure the risk for another seizure is 40%–52% (Berg, 1991). The recurrence risk after two unprovoked seizures is about 80% (Camfield et al., 1985; Hauser et al., 1998; Shinnar et al., 2000). Thirty percent of children with epilepsy will have an incomplete response to medications, and approximately 5%–10% will have intractable epilepsy (i.e., seizures that are frequent despite multiple medications; Ding & Hauser, 2015).

A seizure results from an excessive discharge of a large population of cortical neurons (see Chapter 8). This usually occurs when the excitatory inputs of neurons outweighs the inhibitory inputs. Excessive neuronal firing continues until excitatory neurotransmission is exhausted or the inhibitory networks extinguish it. The seizure usually stops in seconds to minutes, but it may occasionally persist, sometimes requiring urgent medical intervention. When a seizure lasts more than 30 minutes, it is termed *status epilepticus*. The clinical signs and symptoms of the seizure will vary depending on the location of the epileptic discharge in the cerebral cortex and the extent of spread of the discharge in the brain.

Not everyone will have a seizure if presented with the same brain insult because the structural and chemical brain interactions are affected by genetic and acquired factors (Briellmann, Jackson, Tor-boers, & Berkovic, 2001; Frucht, Quigg, Schwaner, & Fountain, 2000). Several factors modulate the predisposition for seizures and the threshold at which they occur. For example, the age of the child and stage of brain development appear to affect the seizure threshold (Moshe, 2000). Some epilepsies are predominantly seen during particular age windows, such as infantile spasms (4–16 months), childhood absence (4–12 years), benign rolandic epilepsy (6–14 years), and juvenile myoclonic epilepsy (8–26 years). The brain undergoes global and regional structural changes over time that involve cortical thickness and myelination (Gage, 2002) as well

as changes in brain chemistry and metabolic rates. Changes in normal brain development, structure, or chemistry can affect the subsequent cascade of brain maturation and predispose the child to epilepsy (Lowenstein & Alldredge, 1998). Repair mechanisms following some brain insults can also lead to the formation of abnormal neuronal networks that may generate seizure activity (Cole, 2000). Brain maturation may explain why some children appear to grow into or out of epilepsy (Sillanpää, 2000).

Seizures are disorders of neuronal transmission and brain network interactions. Factors that may predispose a child to have seizures may include 1) injury to brain cells that make them dysfunctional (e.g., traumatic brain injury, stroke, or brain tumors), 2) disruption of brain cell circuits (e.g., tuberous sclerosis and malformations of cortical development), and 3) alterations in intrinsic brain cell excitability (e.g., inherited epilepsies such as severe myoclonic epilepsy and autosomal dominant nocturnal frontal lobe epilepsy).

The clinical signs and symptoms of seizures usually reflect the function of the brain areas from which they arise or to which they propagate. In the 1989 classification scheme (Commission on Classification and Terminology of the International League Against Epilepsy, 1989), seizures were divided into partial (i.e., focal or localized) and generalized depending on the origin and degree of spread of the seizure activity. Partial seizures were further subdivided into simple and complex depending on whether consciousness was altered. In simple partial seizures, there may be 1) a strange sensation called an aura (e.g., an **epigastric** sensation caused by abnormal neuronal discharge in the mesial temporal lobe of the brain), 2) unusual motor activity (e.g., a jerking of the hands, originating from the primary motor cortex of the frontal lobe), or 3) atypical dystonia-like posturing (resulting from spread of the seizure through the basal ganglia). In complex partial seizures, there is propagation to brain structures that alter the state of consciousness (e.g., through the limbic system). As a result, there may be staring, oral automatisms (lip smacking), or fumbling with hands and clothing. When multiple parts of the brain are involved or there is spread of the electrical discharge to both cerebral hemispheres, generalized tonic-clonic activity may result. In the new classification scheme (Berg et al., 2010; Fisher et al., 2017) seizures are described as generalized or focal, with or without impairment of awareness (replacing simple, complex, secondarily generalized, and primary generalized).

The International League Against Epilepsy (ILAE) has divided epilepsies into three categories: focal epilepsy, generalized epilepsy, and epilepsy syndromes. Epilepsy may also be divided into idiopathic,

symptomatic, and cryptogenic (Commission on Classification and Terminology of the International League Against Epilepsy, 1989). The term *symptomatic* is used when there is a clear structural brain abnormality (e.g., tuberous sclerosis), an acquired cause of epilepsy (e.g., stroke, tumors, or meningitis), or an associated neurological impairment (e.g., intellectual disability or cerebral palsy). *Idiopathic epilepsies* are assumed to be genetic in origin and comprise about 30% of childhood epilepsies (Hauser & Kurland, 1993). In this form of epilepsy, there are no abnormal neurological and neuroimaging findings, and there may be a family history of seizures. The term *cryptogenic* has been used to refer to epilepsies for which a cause cannot be identified. More recently this classification system has been proposed to be amended to 1) *genetic* (replaces idiopathic), when the epilepsy is secondary to a presumed genetic defect (e.g., SCN1A mutation in Dravet syndrome); 2) *structural or metabolic*, when the epilepsy is due to an acquired brain injury (e.g., brain tumor or stroke), a congenital central nervous system malformation, or an inborn error of metabolism (see Chapters 3 and 16), and 3) *unknown cause* (replaces cryptogenic) when the underlying cause is not identified (Berg et al., 2010).

Children with a first seizure of remote symptomatic etiology (i.e., a seizure that is removed in time following a brain insult) tend to have a higher rate of seizure recurrence (approximately 65%; Berg & Shinnar, 1991; Shinnar et al., 1996). Among those with a remote symptomatic etiology, children with static brain dysfunction since birth, such as intellectual disability or cerebral palsy, tend to have the highest rates of seizure recurrence. In contrast to children with remote symptomatic etiology, children with a first seizure of idiopathic or cryptogenic etiology tend to have lower rates of additional seizures, with an approximate 35% risk (Berg & Shinnar, 1991; Shinnar et al., 1996).

The causes of epilepsy vary with age. Malformations of cortical development, perinatal brain injury, and metabolic disorders are common causes of epilepsy in infancy; genetic and congenital disorders are found in early and later childhood; and hippocampal sclerosis (injury/scarring of the hippocampus; Bazendale & Heaney, 2010), alcohol or drug abuse, and trauma may occur in older children and adolescents (Shorvon, 2000).

Classification of Epilepsy and Epilepsy Syndromes

The diagnosis, treatment, and prognosis of seizure disorders depend on the correct identification of the types of seizures and its epilepsy classification. Childhood epilepsies are classified using variations of the ILAE

schema (Commission on Classification and Terminology of the International League Against Epilepsy, 1989).

As mentioned above, the ILAE classifies epilepsy into two major classes: generalized and focal (see Figure 22.1). Other categories include focal-to-bilateral tonic-clonic (a seizure that starts in one side or part of the brain and spreads to both sides), unknown onset, and unclassified (Fisher et al., 2017). Epilepsy syndromes are classified based on the clinical appearance of the seizures, the EEG, and the age of onset. A modified classification system has been developed for some seizures (e.g., neonatal seizures, infantile seizures, and status epilepticus). Another proposed classification system is the 5-axis diagnostic schema, which divides seizures into 1) descriptive ictal terminology, 2) seizure type, 3) syndrome, 4) etiology, and 5) impairment (Engel, 2001). Classifying seizures into different types helps guide further testing, treatment, and estimates of prognosis or outlook.

Occasionally, there is difficulty in classifying epilepsy because 1) the seizure onset is not observed, 2) the focal signs may not be apparent because of the rapid spread of the seizure, or 3) the subtleties of the seizure may be missed because the observers may be so overwhelmed during the event. Fortunately, the interictal (between-seizure) EEG pattern can provide some information on the seizure type (Panayiotopoulos, 1999).

Generalized Seizures

Generalized seizures (those without a clear focal cortical onset) account for more than one third of pediatric epilepsy. They include absence, myoclonic, tonic, clonic, tonic-clonic, and atonic seizures. These seizures have simultaneous bilateral onset, meaning they occur on both sides of the body from the beginning of seizure activity. During generalized seizures, the child may have decreased nonconvulsive motor activity (e.g., the arrest of activity and automatisms seen in absence seizures) or a bilateral synchronous abnormal motor activity (e.g., myoclonic, atonic, or tonic-clonic seizures).

Absence seizures, as described in the case of Patricia, have historically been referred to as “petit mal,” and are characterized by brief episodes of impaired consciousness, usually lasting less than 30 seconds, and without **postictal** confusion (confusion immediately following the seizure episode). These seizures may occur numerous times during the day and can affect the child’s learning ability by interrupting attention and vigilance. Absence seizures are mediated through the thalamus (see Chapter 8), and onset is usually between 3–12 years of age. The classic EEG pattern shows a 3-Hz generalized spike and wave, which can

Focal Onset		Generalized Onset	Unknown Onset

Figure 22.1. Classification of seizures types.¹ (Fisher R. S., Cross J. H., D'Souza C. et al. [2017] Instruction manual for the ILAE 2017 operational classification of seizure types. *Epilepsia* doi:10.1111/epi.13671. [Used with permission]). (Key: ¹Definitions, other seizure types, and descriptors are listed in the accompanying reference, along with a detailed glossary of term. ²These could be focal or generalized, with or without alteration of awareness. ³Due to inadequate information or inability to place in other categories.)

be precipitated by hyperventilation or **photic** (flickering light) stimulation (see Figure 22.2). Sometimes the child may continue to perform a simple automatic activity, such as walking, during the seizure, but is unable to continue a novel task, such as reading aloud. Eye blinking or changes in head and extremity tone may accompany the behavioral arrest (e.g., abruptly stopping reading aloud). Absence seizures cannot be interrupted by verbal or **tactile** (touch) stimulation (Medina et al., 2012). Absence seizures and focal seizures have different features (Table 22.1).

Myoclonic seizures are due to brief contraction of muscles often associated with cortical discharges. They frequently manifest as either a sudden flexion or bending backward of the upper torso and head that lasts less than a second. By contrast, atonic seizures consist of a brief loss of postural tone, which may simulate a fainting spell. While the motor component of both myoclonic and atonic seizures is brief, these seizures

often cluster over the course of a few minutes. Atonic seizures that cause an abrupt loss of postural tone are often referred to as “drop” seizures. Consciousness is usually impaired during these events, and affected children make no attempt to protect themselves when they fall as a consequence of the seizure. As a result, there is an increased risk of head injury. Children with these kinds of seizures may need to wear a protective helmet throughout the day. Following these brief seizures, the child immediately regains consciousness, often crying, seemingly not in pain but upset by the sudden disruption.

Tonic-clonic seizures have been referred to historically as “grand mal” seizures. They may originate from a specific area of the cerebral cortex (focal seizures) that secondarily generalizes, or they may arise bilaterally (primary generalized seizure). Clonic motor activity involves repetitive jerking of arms or legs occurring at a regular rate. Tonic activity consists of sustained

Figure 22.2. Absence seizure.

stiffening/posturing of the extremities. The seizure usually starts with a loss of consciousness, followed by tonic-clonic movements. Respiration may stop briefly, and **cyanosis** (turning blue) and incontinence are common. The EEG shows bilateral spike or polyspike and wave complexes (see below).

Focal Seizures

Focal (formerly termed partial) seizures start in a localized area of the cerebral cortex; they may spread in space and time and may progress to a generalized seizure. They may arise in areas involving motor, sensory, behavioral, autonomic, or cognitive functions (see Figure 22.3). These seizures often begin with an aura and/or an abrupt and unprovoked alteration in behavior. Focal seizures are classified as focal with or without impairment of consciousness or focal-to-bilateral tonic-clonic (Fisher et al., 2017).

A focal seizure without impairment of awareness (previously referred to a simple partial seizure) occurs when the epileptic discharge occurs in a limited region of one cerebral hemisphere and consciousness is

maintained. If the event is merely sensory in nature, it is called an aura. If the seizure spreads and results in an alteration of consciousness, it is referred to as a focal seizure with impairment of consciousness (previously referred to as a complex partial seizure). This may or may not progress to secondary generalization, resulting in a tonic-clonic motor seizure.

Focal seizures with impairment of consciousness are usually accompanied by motor movements such as focal motor jerking, motor arrest, or **automatisms**. Automatisms are involuntary movements that may include eye blinking, lip smacking, facial grimacing, groaning, chewing, fidgeting, or buttoning/unbuttoning movements. Occasionally, as a result of impaired awareness, agitation and anxiety may occur in the confused postictal state.

A focal seizure may spread from one portion of the brain to a contiguous area, resulting in the spread of the shaking to other, adjacent, body parts (called a Jacksonian seizure). If there is a focal onset, occasionally tonic or clonic seizures can be followed by a transient weakness on one side of the body called a Todd's paralysis.

Table 22.1. Comparison of focal seizures and absence seizures

	Focal seizures	Absence seizures
Incidence	Common	Uncommon
Duration	30 seconds–5 minutes	Less than 30 seconds
Frequency of occurrence	Occasional	Multiple times daily
Aura	Yes	No
Consciousness	Partial amnesia and confusion	Immediate return to consciousness
EEG pattern	Focal	Generalized

Figure 22.3. Spread of a focal seizure without impairment of consciousness. A seizure may begin anywhere—in this case, the amygdala of the temporal lobe. The initial feature may be the child smelling an unusual odor. The seizure may stop there or project out to the hippocampus, which might trigger feelings of fearfulness or abdominal queasiness. Memory and visual perception may be affected if the frontal or occipital lobe is involved. The seizure might ultimately extend to the motor strip, resulting in twitching of the limb, which may spread to other limbs or to central structures (causing loss of consciousness), thus becoming a complex partial seizure. Finally, the seizure may cross the corpus callosum to the other cerebral hemisphere and thus be converted from a partial to a generalized seizure.

Epilepsy Syndromes

Epilepsy syndromes are seizure disorders that share signs and symptoms, characteristics, specific EEG features, clinical course, prognosis, response to treatment, and sometimes a common pathogenesis or genetic basis (Wolf, 1994). The epilepsy syndromes fall into two broad categories: localization-related epilepsies and generalized-onset syndromes (Table 22.2). Most children with epilepsy have a predominant seizure type at onset that can be defined. However, only about one third can be assigned to a specific epilepsy syndrome using the most recent proposals for epilepsy syndromes (Wirrell, Grossardt, Wong-Kissel, & Nickels, 2011). A few of the common epilepsy syndromes are discussed below and are organized primarily by age of expression (Table 22.3).

Infantile Spasms Infantile spasms, also known as West syndrome, is characterized by clusters of brief flexor (head, arms, and hip) or extensor (arm and trunk) contractions or spasms, typically associated with distinctive EEG finding, called hypsarrhythmia, and resulting in developmental regression or arrest (Commission on Pediatric Epilepsy of the International League Against Epilepsy, 1992). Infantile spasms are one of the most common forms of epileptic encephalopathy (epilepsy associated with neurocognitive impairment). The peak onset is at 4–7 months of age; 90% of children with this condition have onset before 12 months of age.

An underlying cause or disorder is found in over three quarters of children with infantile spasms (Knupp et al., 2016; Trasmonte & Barron, 1998). Etiologies include neurocutaneous syndromes (especially tuberous sclerosis), metabolic syndromes (e.g., pyridoxine deficiency), genetic syndrome (e.g., Down syndrome), brain malformations of cortical development (e.g., lissencephaly, polymicrogyria, or focal cortical dysplasia), and intrauterine insults (Pellock et al., 2010). Infantile spasms may evolve into Lennox-Gastaut syndrome (LGS) after infancy (see the next section).

A small percentage of children with infantile spasms have a cryptogenic cause (i.e., no identifiable cause). These children tend to respond to therapy (Kivity et al., 2004), have normal development before the spasm onset, and have better epilepsy prognosis and developmental outcomes than children with an identifiable cause.

Early recognition and prompt treatment may improve outcome in infantile spasms. The goal of prompt medical therapy is to normalize the EEG pattern and suppress the seizures. Adrenocorticotrophic hormone and vigabatrin are considered to be the first line of treatment (Mackay et al., 2004). However, high-dose prednisolone has also been used successfully as a treatment option (Lux et al., 2004; Pellock et al., 2010). Vigabatrin is specifically used as a first-choice treatment for children with infantile spasms secondary to tuberous sclerosis (Wheless et al., 2007). ASMs have also been used, including valproate, phenobarbital,

Table 22.2. Epilepsy syndromes and other epilepsies, arranged by age of onset

Neonatal period
Benign familial neonatal epilepsy

Panayiotopoulos syndrome
Epilepsy with myoclonic atonic (previously astatic) seizures
Benign epilepsy with centrotemporal spikes
Autosomal dominant nocturnal frontal lobe epilepsy
Late-onset childhood occipital epilepsy (Gastaut type)
Epilepsy with myoclonic absences
Lennox-Gastaut syndrome
Epileptic encephalopathy with continuous spike-and-wave during sleep
Landau-Kleffner syndrome
Childhood absence epilepsy
Adolescence–adult
Juvenile absence epilepsy
Juvenile myoclonic epilepsy
Epilepsy with generalized tonic-clonic seizures alone
Progressive myoclonic epilepsies
Autosomal dominant epilepsy with auditory features
Other familial temporal lobe epilepsies
Less-specific age relationship
Familial focal epilepsy with variable foci (childhood to adult)
Reflex epilepsies
Distinctive constellations

Berg, A. T., Berkovic, S. F., Brodie, M. J., Buchhalter, J., Cross, J. H., van Emde Boas, W., . . . Scheffer, I. E. (2010). Revised terminology and concepts for organization of seizures and epilepsies: Report of the ILAE Commission on Classification and Terminology, 2005–2009. *Epilepsia*, 51(4), 676–685.

lamotrigine, topiramate, and clonazepam, but they are far less effective than steroids and vigabatrin (except for pyridoxine [vitamin B₆] for pyridoxine-dependent seizures; Ito, 1998). In some instances of refractory infantile spasms with focal seizures (called facilitated spasms) or with a single seizure focus identified, epilepsy surgery maybe an option (Shields et al., 1999).

Lennox-Gastaut Syndrome Infantile spasms may evolve into Lennox-Gastaut syndrome (LGS). This disorder is defined by a mixture of seizure types consisting of atypical absence, tonic, drop or atonic, myoclonic,

Table 22.3. Seizure types by age of occurrence

Seizure/epilepsy type	Age of occurrence
Febrile seizures	6 months–6 years
Infantile spasms	4–16 months
Benign rolandic epilepsy	6–14 years (peak at 5–8 years)
Juvenile myoclonic epilepsy	8–26 years (peak at 14 years)
Childhood absence	4–12 years
Lennox-Gastaut syndrome	1–5 years
Juvenile absence epilepsy	7–17 years (peak at 14 years)

tonic-clonic, and focal seizures with an impairment of awareness. Children with LGS are at an increased risk for frequent falls and injury. The characteristic EEG features include slow background activity, anterior slow spike waves, and multifocal spikes. Both seizure control and resolution of EEG abnormalities appear to be necessary for improved cognitive and behavioral outcome. Unfortunately, the seizures are difficult to control, and most affected children manifest intellectual disability.

Landau-Kleffner Syndrome Landau-Kleffner syndrome, also called acquired epileptic aphasia, is a disorder of childhood characterized by a loss of language skills in association with EEG abnormalities. It is characterized by an **auditory agnosia** (inability to distinguish different sounds in the presence of normal hearing), language regression, and behavioral disturbances that include inattention. These symptoms may develop gradually over months. The EEG pattern shows continuous abnormal epileptiform activity activated by sleep and obscures the normal sleep pattern (Inutsuka et al., 2006; Tassinari et al., 2012). The goal for treatment is normalization of the EEG and control of overt clinical seizures. Several ASMs can be tried, and steroids may be useful. However, while medication may resolve the EEG abnormalities, the aphasia may persist. Prognosis is variable; some children may recover some function after several years, while others are left with permanent speech impairments.

Juvenile Myoclonic Epilepsy Juvenile myoclonic epilepsy (JME) commonly begins during adolescence and is manifested by myoclonic jerks that occur upon awakening. More commonly, these myoclonic jerks are overlooked and, until a generalized tonic clonic occurs, medical attention is not sought. The seizures are exacerbated by alcohol ingestion, sleep deprivation, and photic stimulation. JME is likely genetically mediated, and individuals with JME have typical intelligence. In terms of treatment, ASMs that are effective for generalized rather than focal seizures are indicated,

such as valproate and lamotrigine (Montalenti et al., 2001; Wallace, 1998). Previously, individuals with JME were thought to require lifelong treatment with an ASM. However, in a long-term follow-up study, one third of participants experienced seizure remission over time and lifelong ASM treatment was not needed (Camfield & Camfield, 2009).

Benign Epilepsy Syndromes The most common idiopathic benign epilepsy syndrome of childhood is **benign childhood epilepsy with centrotemporal spikes (BECTS)**, also referred to as benign Rolandic epilepsy (BRE). This syndrome usually begins at 3–12 years and causes focal seizures without impairment of awareness. The seizures typically start in the region of the cortex that controls mouth and face movements, occur at sleep onset or at arousal, and can generalize. When the seizure starts in sleep, the focal onset is unobserved, so children may appear to be having generalized tonic-clonic seizures (Lerman, 1992). The characteristic EEG abnormality is epileptic spikes that are seen at the centrotemporal areas of the brain (Figure 22.4). Treatment is often not needed, and these syndromes are not associated with long-term sequelae. Some studies, however, have found an increased incidence of language and reading disabilities in affected children (Fejerman et al., 2000).

A second seizure type in this grouping is **benign occipital epilepsy**. It is characterized by visual disturbances and may be accompanied by vomiting, headache, eye blinking, and alteration of consciousness. At times it may be difficult to differentiate from migraine

headaches. Unlike BRE, one half of children with benign occipital epilepsy will not outgrow their seizures. **Panayiotopoulos syndrome**, which also exhibits occipital epileptiform discharges, is characterized by brief, paroxysmal, and varying autonomic signs and symptoms.

Febrile Seizures Febrile seizures are the most common seizures occurring at the pediatric age group. They are not considered an epilepsy syndrome because the seizures are provoked. Febrile seizures occur in approximately 5% of children between the ages of 6 months and 5 years (Nelson & Ellenberg, 1978). They generally occur with body temperature elevations above 39° Celsius (102° Fahrenheit). Those that occur with lower temperatures are associated with an increased risk for having recurrent febrile seizures (Berg, Daresky, Holford, & Shinnar, 1998). Acute illnesses such as upper respiratory illnesses, middle ear infections, and viruses associated with skin rashes (e.g., roseola) are frequent precipitants of febrile seizures.

Febrile seizures occur in two forms: simple febrile seizures, which manifest as a single generalized tonic seizure lasting less than 15 minutes (usually much less than this) and occurring during an acute illness, and complex febrile seizures, which are prolonged, focal, and/or recurrent during a single illness (Shinnar & Glauser, 2002; Seinfeld & Pellock, 2013). Febrile seizures tend to be familial and thus are postulated to have a genetic basis (Audenaert, Van Broeckhoven, & De Jonghe, 2006). In an affected child, the risk for a febrile seizure occurring in a sibling is 10%; if a parent also

Figure 22.4. Centrotemporal spikes typical of benign childhood epilepsy with centrotemporal spikes (also referred to as benign rolandic epilepsy).

has a history of febrile seizure, the risk for that sibling increases to 50%.

In a child who presents with a febrile seizure, the risk of a subsequent febrile seizure is 30%–50% depending on the child's age at the time of the first seizure, the presence of a family history of febrile seizures, and the degree of fever (Berg et al., 1992). After a simple febrile seizure, the risk of developing epilepsy by school age is 1%; the risk of epilepsy is 2%–3% following a complex febrile seizure (Nelson & Ellenberg, 1976). The risk of developing epilepsy later increases if there is a family history of epilepsy or if the child has a developmental disability such as cerebral palsy, autism, or intellectual disability (Nelson & Ellenberg, 1976). In some studies, a febrile seizure with focal features or febrile status epilepticus has been associated with the development of temporal lobe epilepsy. As many as 30%–50% of adults with refractory temporal lobe epilepsy associated with **mesial temporal sclerosis** (scarring of the hippocampus) have a history of febrile seizures (Bower et al., 2000). By contrast, children with frequent but brief generalized seizures are more likely to have a genetic cause. For example, mutations of the *SCN1A* gene, which mediates neuronal firing, is the underlying cause of the syndrome known as generalized epilepsy with febrile seizures plus, as well as Dravet's syndrome (which is associated with truncation mutations of the *SCN1A* gene).

For prevention of febrile seizures in susceptible children, parents are taught to treat fever aggressively and promptly with antipyretics (medications for fever, such as acetaminophen). Prophylactic ASMs are usually not recommended since the benefits of intervention do not outweigh the risks of adverse effects from long-term use of medication. Although treatment may prevent subsequent febrile seizures, ASMs do not prevent the development of future epilepsy, and they may interfere with learning and attention (Knudsen, 2000). An alternative to chronic ASMs treatment is acute management with rectal or nasal benzodiazepines at the time of the seizure, which may abort a prolonged febrile seizure or prevent clusters of febrile seizures.

Conditions That Mimic Epilepsy

There are a number of conditions that mimic seizures but are nonepileptic events because they do not involve abnormal discharges of the cortical neurons (see Conditions That May Mimic Epilepsy textbox). They are caused by either physiological or psychological conditions. One study showed that approximately 20% of referrals for video EEG monitoring are not found to have epileptic seizures (Udall et al., 2006). In general, if a behavior can be triggered, interrupted, or modified

by external stimuli, then it is probably not a seizure. A few examples are discussed in detail below.

Most random movements seen during sleep are a part of normal sleep activity. These include the random jerks of the extremities or eyes (rapid eye movements) that occur during active sleep, when the child is dreaming. Occasionally, sleep movements can be confused with seizures. **Benign sleep myoclonus of infancy** occurs in newborns and infants during sleep, and these movements disappear on arousal (Pachatz, Fusco, & Vigeveno, 1999). It is characterized by a brief arrhythmic twitching of a limb during sleep that may be mistaken for a seizure; the EEG is normal, however, during this behavior.

Other more complex motor behaviors may occur 1–2 hours after sleep onset or occasionally upon arousal. These parasomnias include night terrors, sleep talking, sleep walking, and teeth grinding (Laberge, Tremblay, Vitaro, & Montplaisir, 2000). Rarely, nocturnal frontal lobe seizures are misinterpreted as a parasomnia (see Chapter 28); a video EEG recording is required to distinguish between the two (Lombroso, 2000). During a parasomnia, the eyes are open and the child appears to be awake, but the EEG shows a normal sleep rhythm. These parasomnia episodes may last as long as 15–30 minutes, much longer than a typical seizure, and parents may be unable to end the spell or rouse the child during this time. Rarely, treatment with medication such as diazepam (Valium) is necessary if the behavior is significantly disruptive to family life.

Psychogenic nonepileptic seizures (PNESs) usually present with generalized or subtle motor movements, an abrupt return to consciousness, no post-episode tiredness, and a normal EEG pattern. These spells may occur in an individual with affective and anxiety disorders (Kutluay et al., 2010; Patel, Scott, Dunn, & Garg, 2007). Features that suggest PNES include asynchronous movements that wax and wane, rolling from side to side, pelvic thrusting, eye closure during the spell, and absence of postictal confusion (Avbersek & Sisodiya, 2010). Video EEG monitoring with the goal of capturing the spells is often necessary.

Behaviors such as staring spells and rage attacks can be mistaken for seizures. Brief staring spells (daydreaming or “spacing out”) are most commonly a sign of inattention but may resemble absence seizures. Staring spells, however, lack the subtle motor changes seen with absence or focal seizures (Bye, Kok, Ferenschild, & Vles, 2000). In temper tantrums and rage attacks, the child yells, throws himself on the floor, and lashes out at nearby people (Gordon, 1999). This may be associated with sweating, paleness, and dilated pupils. Although a similar dyscontrol syndrome (intermittent explosive disorder) has been seen following frontal or

temporal lobe brain injury, ictal (seizure-associated) rage is usually unprovoked, very rare, and not directed toward a person (Pellock, 2015). After a rage attack the child resumes a normal state and may express remorse, while after an ictal event the child does not remember the episode (Pellock, 2015).

Breath-holding spells typically occur in infants between 6–18 months of age and are accompanied by loss of consciousness and generalized convulsions. The child becomes upset and cries vigorously, followed by an arrest in breathing. If the breath holding lasts long enough, it may result in a brief loss of consciousness followed by rapid neurological recovery. In **pallid infantile syncope**, the child faints or convulses after a startling, often minor injury. This presumably results from an exaggerated vasovagal reflex. Occasionally, a prolonged breath-holding or **syncopal** (fainting) episode can be associated with brief generalized convulsions followed by lethargy (Kuhle, Tiefenthaler, Seidl, & Hauser, 2000). There is, however, no epileptic activity on the EEG during these episodes.

Sandifer syndrome, which is associated with sudden arching of the back and rigid posturing of the trunk and upper extremities in infants, is caused by symptomatic gastroesophageal reflux and esophagitis (Frankel, Shalaby, & Orenstein, 2006). It may appear similar to infantile spasms and tonic seizures. The condition is addressed by treating the underlying gastroesophageal reflux with thickened feedings or medications.

Abnormal movements, termed **brainstem release phenomena**, can also be seen in neonates and children who are neurologically disabled. These non-epileptic motor phenomena arise from brainstem centers as a consequence of the reduction of neocortical inhibitory inputs secondary to diffuse encephalopathy (e.g., brain injury in premature infants with intraparenchymal hemorrhage or hypoxic ischemic encephalopathy; see Chapter 5). These movements may include subtle posturing, stiffening, brief deviation of the eyes, cessation of normal motor activity, apnea, or autonomic symptoms (Tharp, 2002). These movements may be difficult to differentiate from seizures; a video EEG may be helpful in distinguishing between the two. Brainstem release phenomena also have features of reflexive behavior, such as being provoked by stimulation and suppressed by gentle restraint (Mizrahi, 2016).

Conditions That May Mimic Epilepsy

- Migraine headaches
- Movement disorders: tic disorders, paroxysmal kinesogenic choreoathetosis
- Breath-holding spells

- Shuddering
- Sandifer's syndrome
- Parasomnias and normal physiological movements in sleep
- Sleep disorders: narcolepsy-cataplexy, night terrors
- Behavioral disorders
- Rage attacks, inattentiveness of ADD
- Panic attacks and hyperventilation
- Psychogenic non-epileptic seizures
- Syncope and other cardiac dysrhythmias/valvular disease/autonomic dysfunction
- Hyperexplexia (exaggerated startle response)
- Brainstem release phenomena
- Gastroesophageal reflux

DIAGNOSIS AND EVALUATION

The diagnosis of epilepsy begins with the clinical history and examination. A detailed description of the suspected seizure is crucial. The history should also include the presence or absence of aura; level of responsiveness during the event; and post-ictal changes, including altered mental status and transient focal neurologic deficits (i.e., Todd's paralysis). Tongue biting and urinary or bowel incontinence during the episode suggests seizure as its cause. Acute seizure precipitants, including infection, trauma, and drugs (illicit or accidental ingestion), need to be explored. The history helps to distinguish seizures from seizure mimics and to classify the seizure type. An infant or young child who turns blue or pale and loses consciousness after being upset or hurt likely has had a breath-holding spell. The presence of an aura or Todd's paralysis suggests a focal seizure. In children who present with a generalized tonic-clonic convulsion, an initial rapid head turn or eye deviation to one side suggests a focal seizure with the epileptogenic focus located in the contralateral brain hemisphere. A staring spell that lasts for a minute or more followed by post-ictal altered mental status (e.g., confusion, lethargy) points to a focal seizure. On the other hand, brief staring spells lasting a few seconds with return to full consciousness immediately afterward suggest absence seizures. Staring could also be a manifestation of non-epileptic events like daydreaming and inattention. About half of non-epileptic events captured on EEG monitoring are staring episodes (Uldall et al., 2006). The physical and

neurologic examination may identify an acute illness or an associated neurologic disorder. Attention should be paid to head circumference, the skin exam (looking for evidence of **phakomatoses**; i.e., genetic conditions with characteristic skin findings), and focal neurological deficits.

Routinely performing laboratory tests is not helpful in a well child who has recovered from a brief seizure. Electrolytes should be collected, however, in children younger than 2 years of age to check for abnormal sodium, calcium, and glucose levels. Glucose should be checked in all individuals in status epilepticus and in people who have a history of seizures with fasting. Similarly, performing a **lumbar puncture** (spinal tap) should be reserved for febrile children with prolonged altered consciousness or who have suspected meningitis or encephalitis (De Hertz et al., 2000). In children with continuing neurologic impairment after a seizure, further workup, including lumbar puncture, chemical panel, metabolic tests for inborn errors of metabolism (e.g., plasma amino acids, urine organic acids, lactate, pyruvate), brain imaging (computed tomography [CT]/magnetic resonance imaging [MRI]), and EEG to rule out nonconvulsive status epilepticus, needs to be considered.

A sleep-deprived EEG is indicated in the workup of all children suspected of having seizures. To perform the EEG several recording electrodes are placed on the scalp at set points over the frontal, central, parietal, temporal, and occipital regions bilaterally. These electrodes record voltage changes from the cortex below. The EEG displays electrical potential differences between neighboring electrodes or between an electrode and a reference. The EEG provides information regarding background brain electrical activity (e.g., generalized or focal slowing, which suggests diffuse or focal cerebral dysfunction, respectively), the presence or absence of epileptic discharges (sharp waves or

spike and wave discharges indicating cortical hyperexcitability and, hence, predisposition to seizure), and response to activating procedures (hyperventilation, photic stimulation, and sleep deprivation). Occasionally seizures can be captured or provoked by activating procedures during a routine/standard EEG. The EEG should be recorded during wakefulness and light sleep. Light sleep tends to activate epileptiform discharges and increases the yield of the EEG.

EEG findings, along with the clinical data, help to establish the diagnosis of a specific seizure type. For instance, the finding of 3-Hz generalized spike and wave discharges activated by hyperventilation is diagnostic of absence epilepsy (Figure 22.2). Centrottemporal spike and wave discharges activated in sleep suggest benign childhood epilepsy with centrottemporal spikes (Figure 22.4). The EEG may also provide prognostic information. In children with their first unprovoked seizure who have a normal neurologic examination, the seizure recurrence risk is higher if the EEG is abnormal (Shinnar et al., 1996). In situations where the nature of the events is unclear, continuous video EEG monitoring for 23 hours or longer may be needed to capture and characterize the events. Continuous video EEG is required as part of presurgical evaluation in children for whom epilepsy surgery is being considered (see Box 22.2 for a discussion of the role of the epilepsy specialist, or epileptologist, in the diagnosis and management of complex epilepsy).

Brain imaging with MRI is essential to identify structural lesions that cause seizures. In some epilepsy syndromes such as benign childhood epilepsy with centrottemporal spikes (benign rolandic epilepsy), childhood or juvenile absence epilepsy, and juvenile myoclonic epilepsy, the likelihood of a structural lesion is low and routine neuroimaging is not indicated unless atypical features are present or the clinical course is atypical. Children with simple febrile seizures do

BOX 22.2 INTERDISCIPLINARY CARE

The Epileptologist

An epilepsy specialist (epileptologist) is a neurologist with expertise in epilepsy. For children with epilepsy who do not respond to one or two first-line anti-seizure medications, evaluation by an epilepsy specialist is advisable. The epilepsy specialist will review the seizure history, EEG, and brain MRI. In a child who continued to have seizures after two or more appropriately selected anti-epileptic drugs, the chance of success with another anti-epileptic drug is low. The epilepsy specialist will explore other treatment options, including dietary treatment, surgery, and neuro-modulatory therapies. As the first step the child is admitted to an inpatient video EEG monitoring unit to capture and characterize the child's typical seizures. If surgery is an option to a specific child, the next step is to present and discuss this in a multidisciplinary epilepsy surgical conference. Clinical, EEG, MRI, and neuropsychology findings will be reviewed, and the multidisciplinary team will then determine whether the child is a surgical candidate.

not require routine brain imaging (Subcommittee on Febrile Seizures—American Academy of Pediatrics, 2011). In all other children with recently diagnosed focal or generalized epilepsy and in children younger than 2 years of age, neuroimaging is recommended (Gaillard et al., 2009; Hsieh et al., 2010). The preferred imaging modality is brain MRI because of higher yield and better anatomic detail. High-resolution brain MRI should be performed with epilepsy and age-appropriate protocol (Gaillard et al., 2009). Head CT is usually performed in the emergency room setting; it may identify tumors, bleeding, and calcifications, but it may also provide falsely reassuring negative results.

Functional neuroimaging (see Chapter 8) studies are also used to identify the seizure focus when epilepsy surgery is being considered and a routine MRI is normal. FDG-positron emission tomography (FDG-PET) assesses the interictal brain metabolism. A seizure focus tends to have low metabolism in the interictal period. Interictal and ictal single photon emission computed tomography (SPECT) assesses blood flow to the brain and may therefore be able to identify the seizure focus. Magnetoencephalography (MEG) helps in localizing epileptiform discharges. Functional MRI is a noninvasive technique used to identify functionally critical (“eloquent”) brain regions to be spared during epilepsy surgery, such as those that subserve language, motor, sensory, and memory functions (O’Shaughnessy, Berl, Moore, & Gaillard, 2008). Magnetic resonance spectroscopy (MRS) performed along with MRI is used to assess the concentration of some chemicals (e.g., N-acetyl aspartic acid, choline, creatine, and lactate) in specific brain regions and is helpful in the workup of certain metabolic disorders (e.g., an abnormal lactate peak may be seen in mitochondrial disorders).

TREATMENT

Once the diagnosis of epilepsy is made and an evaluation is initiated for etiology, then treatment is pursued. ASMs are the first line of treatment in almost all instances of epilepsy. The ideal ASM will control, and hopefully prevent, seizures and correct the underlying epileptogenic tendency without producing adverse effects. However, none of the currently available ASMs meets this standard. The decision to start ASMs treatment in a person with epilepsy is based on balancing the risk of recurrence of seizures, the potential harm involved with occurrence of a seizure, and the adverse effects of ASMs.

The risk of recurrence of seizure after a single unprovoked seizure is 40%–50% (Berg, 2008). It tends to be higher in children with symptomatic causes, an abnormal EEG, a history of febrile seizure, Todd’s

paralysis, and seizures in sleep (Berg, 2008; Shinnar et al., 1996). About half (53%) of seizure recurrences occur in the first 6 months after the initial seizure, and 88% within 2 years (Shinnar et al., 1996).

The seizure recurrence risk increases to 65%–79% after two unprovoked seizures (Camfield et al., 1985; Hauser et al., 1998). Although initiating ASMs may delay the recurrence of seizures, postponing initiating ASMs until the second seizure does not appear to alter the ultimate prognosis, the risk of brain injury, or the efficacy of ASMs (Arts & Geerts, 2009; Hirtz et al., 2003). A child who has two or more unprovoked seizures should be considered for initiation of ASM. However, treatment should be individualized, and some children with self-limiting epilepsy syndromes like BECTS may not need to be on ASMs even if they have two or more seizures as long as the seizures are infrequent, nocturnal, and manifest as simple partial seizures.

Prehospital Management of Acute Seizures

Children with epilepsy and their families need to be educated about common sense seizure precautions (see the Seizure Precautions: Common Sense Measures textbox). Activities that could potentially result in significant injury or endanger the life of a child who is having a seizure should be avoided.

First aid measures and emergency plans should be discussed with parents and with the school nurse. Children in the midst of a generalized tonic-clonic convulsion (“grand mal seizure”) should be placed on a flat surface and turned to one side to prevent aspiration. Tight clothes should be loosened around the neck. No object should be placed between the teeth. The airway should be maintained (for example, by pulling the jaw forward using a jaw-thrust maneuver). Cardiopulmonary resuscitation is usually not needed.

Seizures usually last less than 5 minutes; however, if they persist over 5 minutes they tend to continue for longer periods of time unless there is intervention (Shinnar et al., 2001). If seizure lasts 5 minutes or longer, rectal diazepam gel (Diastat) should be given at home. Intranasal or **buccal** (into-the-cheek) midazolam (Holsti, Dudley, & Shunk, 2010; Scott, Besag, & Neville, 1999) and dissolving clonazepam wafers placed between the cheek and gum (Troeser, Hastriter, & Ng, 2010) are alternatives to rectal diazepam with comparable efficacy and improved ease of use. The family should be educated about the use of the selected emergency medication. Urgent medical attention (i.e., calling 911) is recommended if the child has no known prior seizures, if seizure clusters are unresponsive to medications, if consciousness is not regained following the seizure, or if there is another significant intercurrent illness.

Seizure Precautions: Common Sense Measures

- Take showers instead of baths
- Leave bathroom doors unlocked
- Avoid climbing heights (e.g., trees, ladders)
- Wear a helmet while riding a bicycle or scooter
- Swim in a clear water ONLY with adult supervision
- Ensure parental supervision around hot objects (e.g., stoves) to avoid burn injury

Chronic Management of Epilepsy: Anti-seizure Medications

Mechanisms, Selection, and Use of ASMs

ASMs act on excitatory (glutamate-mediated) and inhibitory (gamma aminobutyric acid [GABA]-mediated) neurotransmission in cortical neurons through one of four mechanisms: 1) modulation of voltage-gated sodium channels (phenytoin, carbamazepine, felbamate, lamotrigine, topiramate, oxcarbazepine, and zonisamide), 2) modulation of calcium channels (ethosuximide, zonisamide, and valproic acid), 3) enhancing GABA action (benzodiazepines, barbiturates, tiagabine, and vigabatrin), and 4) inhibiting glutamate (topiramate and felbamate). Many ASMs exert their effect through multiple mechanisms of action (Sankar & Holmes, 2004). Selection of an ASM is based primarily on seizure type (focal versus generalized), epilepsy syndrome, side effect profile, and comorbidities (Wolfgang, 2007).

ASMs are broadly categorized as narrow spectrum (carbamazepine, gabapentin, lacosamide, oxcarbazepine, phenobarbital, phenytoin, and tiagabine) and broad spectrum (lamotrigine, levetiracetam, rufinamide, topiramate, valproate, and zonisamide). The narrow-spectrum drugs are effective in focal or secondarily generalized epilepsies, while broad-spectrum ASMs are effective in

both focal and generalized epilepsies (Asconape, 2010). Table 22.4 shows the selection of ASMs based on seizure type, and the characteristics of individual ASMs can be found in Appendix C. Carbamazepine, oxcarbazepine, leviteracetam, and lamotrigine are first-line drugs in focal seizures with or without secondary generalization, while valproate, lamotrigine, topiramate, and perhaps leviteracetam are first-line drugs in generalized epilepsies (Wheless, Clarke, & Carpenter, 2005; Wilmshurst, Burman, Gaillard, & Cross, 2015; Shih et al., 2017). For Lennox-Gastaut syndrome, additional medication options include rufinamide, clobazam, and felbamate.

Valproate, pregabalin, and carbamazepine are associated with weight gain, while topiramate and zonisamide result in weight loss. When treating individuals who are obese and need to avoid weight gain, topiramate or zonisamide may be preferred choices of ASMs.

Because epilepsy is also comorbid with a range of other neurological conditions and because seizure medications are also effective in a range of other conditions, it is frequently possible to use a single medication to treat epilepsy and its comorbidity. An individual with migraine and epilepsy could be treated for both conditions with topiramate or valproate. Carbamazepine, lamotrigine, and valproate are appropriate choices for individuals with an associated mood disorder. Phenobarbital and topiramate, on the other hand, are associated with depression and are best avoided in people with mood disorders.

The goal of ASM treatment is prevention of seizures while having no or minimal side effects and resulting in an acceptable quality of life (QOL). In children with refractory epilepsy, acceptable seizure control should be defined and agreed upon between the older child, his or her parents, and the health care provider. Many parents will tolerate a few seizures if it means a more alert child with a lower ASM dose and fewer drugs.

Table 22.4. Selection of anti-seizure medications (ASMs) based on seizure types

Seizure type	First-line ASMs
Partial or secondarily generalized epilepsy	Carbamazepine, oxcarbazepine, leviteracetam, lamotrigine
Generalized epilepsy	
Absence	Ethosuximide, lamotrigine, valproate
Juvenile myoclonic epilepsy	Valproate ^a , lamotrigine, topiramate
Tonic clonic	Valproate ^a , lamotrigine, topiramate
Lennox-Gastaut syndrome	Valproate ^a , lamotrigine, topiramate
Infantile spasms	Adrenocorticotrophic hormone, vigabatrin ^b

Adapted from Wheless, J. W., Clarke, D., Arzimanoglou, F., & Carpenter, D. (2007). Treatment of pediatric epilepsy: European expert opinion, 2007. *Epileptic Disorders*, 9(4), 353–412.

^aThe risk of valproate-induced hepatic toxicity is high in children less than 2 years of age.

^bVigabatrin is the treatment of choice in children with tuberous sclerosis.

ASMs should be started at a low dose and titrated up slowly to the lowest effective dose. Whenever possible, monotherapy is the preferred treatment. **Polypharmacy** (the use of multiple medications) increases the risk of adverse effects and drug interactions. If two or more appropriate ASMs used at reasonable doses have failed an individual with a focal epilepsy, then other treatment modalities (e.g., surgery or the ketogenic diet; see discussion below) should be considered. Once a child is started on ASMs, the child should be monitored for adverse effects. Monitoring drug levels can be useful 1) to assess adherence to treatment, 2) to know the individual's effective therapeutic drug level for future comparisons, 3) to diagnose clinical toxicity, and 4) to adjust dose (Patsalos et al., 2008).

ASM Adverse Effects Prior to 1993, carbamazepine, ethosuximide, phenobarbital, phenytoin, and valproate were the principal ASMs available for use. Since 1993, many new ASMs have been introduced, including felbamate, gabapentin, lacosamide, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, rufinamide, tiagabine, topiramate, zonisamide, and vigabatrin. The newer ASMs as a group have an efficacy comparable to the older drugs in controlling seizures and many have a better side-effect profile.

ASM adverse effects fall in to one of three categories: 1) dose-related adverse effects, 2) idiosyncratic reactions, and 3) chronic adverse effects (Perucca & Meador, 2005). Dose-related adverse effects often impact the central nervous system and manifest as somnolence, dizziness, ataxia, and cognitive impairment. These adverse effects can be minimized by starting with a low dose of ASM and titrating up slowly to the lowest effective dose. Idiosyncratic reactions (rare reactions in specific individuals) include **urticaria** (hives), Stevens-Johnson syndrome (a severe immune reaction associated with blister and peeling of the skin and mucous membranes), hepatitis, and aplastic anemia. Chronic adverse effects like weight change, gingival hyperplasia, hair loss, and abnormal bone metabolism may be seen with prolonged use of ASMs (Perucca & Meador, 2005). When adverse effects occur, the dose of the ASM should be decreased or stopped if the reaction is severe.

ASM-related cognitive adverse effects are especially important in young children who are acquiring new skills, and they may result in long-lasting developmental impairment (Loring & Meador, 2004). ASMs predominantly affect attention and psychomotor speed (Hessen et al., 2006; Lagac, 2006; Loring & Meador, 2004). Although all ASMs may potentially cause cognitive adverse effects, particularly at high doses and in the presence of polypharmacy (Perucca & Meador, 2005),

phenobarbital and topiramate seem to be incriminated more often than others (Park & Kwon, 2008). There is concern that the cognitive impairment associated with phenobarbital may be long lasting (Sulzbacher et al., 1999). Cognitive adverse effects of topiramate tend to occur with higher doses, rapid titration, and polypharmacy (Glauser et al., 2007; Park & Kwon, 2008). Leviteracetam is associated with reversible deterioration in behavior and occasionally psychosis. Behavioral adverse effects of leviteracetam are the most common reason for discontinuation of therapy (Egunslola, Choonara, & Sammons, 2016). Perampanil is associated with a higher risk of psychiatric adverse effects including aggression, suicidal ideation, and depression. The risk of these serious psychiatric adverse effects is higher for higher doses and in adolescents as compared with adults (Rugg-Gunn, 2014).

Drug Interactions ASMs that induce hepatic enzymes (e.g., carbamazepine, phenytoin, and phenobarbital) or inhibit hepatic enzymes (e.g., valproate) that are important in drug metabolism (e.g., cytochrome P450 [CYP450] enzymes, glucuronyl transferase, and epoxide hydrolase) may affect the levels of other concomitantly used ASMs or their metabolites as well as other classes of drugs (Perucca & Meador, 2005). Enzyme-inducing ASMs reduce the concentration of other ASMs metabolized by the hepatic enzyme system, in some instances to a significant degree. For example, valproic acid inhibits the metabolism of lamotrigine and may result in higher plasma levels, thus increasing the risk of adverse effects of lamotrigine, especially Stevens-Johnson syndrome. To prevent such adverse effects, lamotrigine should be started at a very low dose, titrated up slowly, and maintained at a relatively lower dose in children taking valproic acid.

Other drugs can also affect the hepatic enzyme systems. Erythromycin and clarithromycin, for instance, inhibit CYP450 enzymes, and as a result, children taking carbamazepine may develop toxicity if either of these antibiotics is concomitantly administered.

Anticipating potential drug interactions, avoiding drug combinations with significant interactions, adjusting doses, monitoring for adverse effects of drugs, and monitoring blood levels of ASMs will help prevent drug toxicity or loss of efficacy due to drug interactions. It is also important to anticipate a significant change in the blood level of ASMs as a concomitantly administered enzyme inducer or inhibitor is discontinued. In children with cancer who require chemotherapy, avoiding enzyme-inducing ASMs and selecting ASMs with little or no hepatic enzyme-inducing effects is desirable, as ASMs may enhance the metabolism of chemotherapeutic agents.

ASMs and Bone Metabolism Chronic use of ASMs may be associated with abnormal bone metabolism. ASMs that induce hepatic cytochrome P450 enzymes accelerate vitamin D metabolism and may cause a vitamin D deficiency (Shellhaas & Joshi, 2010). Laboratory tests (25-OH vitamin D) and imaging studies (DEXA scan) to assess bone metabolism should be monitored in children with prolonged ASM therapy. Multivitamins with calcium and vitamin D are recommended in this group of children.

ASMs in Adolescent Women There are two major concerns in the treatment of adolescent women with epilepsy. One is loss of efficacy of contraception in individuals who are taking certain ASMs (including carbamazepine, phenytoin, phenobarbital, and topiramate, at high dose). These drugs increase the metabolism of estrogen and protein binding of progesterone. In these instances, increasing the estrogen dose and using barrier methods need to be considered to prevent unwanted pregnancy (Zupanc, 2006).

A second concern is **teratogenesis** (adverse effects on the developing fetus; see Chapter 2). Most ASMs are pregnancy category C (teratogenicity in experimental animals, no human studies). With all ASMs, the risk of congenital malformations is higher than the general population (Asconape, 2010), and polytherapy may further increase this risk (Vajda et al., 2016), yet risk-benefit analysis favors continuation of most ASMs during pregnancy. Valproate and phenobarbital, however, tend to be associated with a higher incidence of congenital malformations and are better avoided in pregnancy. Valproate demonstrates a dose-dependent increased risk of major congenital malformations (Tomson et al., 2015), particularly neural tube defects (e.g., spina bifida). Supplementation with folic acid may reduce this risk and is recommended for all women with pregnancy potential (see Chapter 6). Topiramate in polytherapy may also be associated with an increased risk of major congenital malformations (Vajda et al., 2016).

A study that compared the effect of in utero exposure of carbamazepine, lamotrigine, phenytoin, and valproate on IQ at 3 years of age showed that valproate was associated with a significantly increased risk of cognitive impairment and autism (Meador et al., 2010).

Discontinuing ASMs There are a number of concerns about the long-term use of ASMs. These include teratogenicity, poor self-image of being chronically ill, adverse effects of drugs, and cost. As a result, practitioners attempt to stop ASMs after a sufficiently long period of seizure freedom. An EEG is performed when a decision about stopping an ASM is considered; a

normal EEG is reassuring, while an abnormal EEG introduces a level of uncertainty about seizure recurrence risk. The risk of seizure recurrence after discontinuation of ASMs in a child who has been seizure free for 2 years or longer is 25%–36% (Caviedes & Herranz, 1998; Shinnar et al., 1994). Children with symptomatic causes and certain developmental disabilities have a lower rate of seizure freedom after discontinuation of ASMs (20%–50%). Medications should be tapered over several months and not abruptly discontinued, as this may precipitate seizures.

Chronic Management of Epilepsy: Other Treatment Options

In the chronic management of epilepsy, pursuing other treatment options may be necessary for children who do not respond to appropriate ASMs.

Ketogenic Diet The ketogenic diet mimics the fasting state and is a high-fat, low-carbohydrate, and low-protein diet. It is restrictive. The ketogenic diet is the treatment of choice for glucose transporter deficiency, a condition associated with epileptic encephalopathy resulting from impaired glucose transport to the brain (Klepper, 2008). The ketogenic diet is also used in the treatment of pyruvate dehydrogenase deficiency (a mitochondrial disorder; see Chapter 16). Children with a wide variety of seizure types and syndromes refractory to ASMs benefit from the ketogenic diet. (Freeman, Kossoff, & Hartman, 2007). Urine and blood ketone levels should be monitored to ensure adequate ketosis. Side effects include metabolic acidosis, hypoglycemia, gastrointestinal disturbance, and lethargy in the early stages of initiating the diet. Renal stones, dyslipidemia (abnormalities of lipid metabolism), and failure to thrive are late side effects (Freeman et al., 2007). The diet can be stopped after a child is seizure free for a sufficiently long time in much the same way as discontinuation of ASMs.

Surgical Resection of Epileptic Focus In children with focal epilepsy who have failed two or more appropriate ASMs at an adequate dosage, epilepsy surgery should be considered. After the third medication, the likelihood of additional medications working is only 4%–8%. When a clear focal lesion is present (e.g., mesial temporal sclerosis, focal cortical dysplasia, developmental tumors, or vascular malformations) the likelihood of an excellent outcome from surgery is 80%–85% (50%–60% seizure free, 25%–30% rare seizures; Chern, Patel, Jea, Curry, & Comair, 2010; Englot, Breshears, Sun, Chang, & Auguste, 2013; Englot et al., 2013; Jobst & Cascino, 2015; Rowland et al., 2012). If the

MRI is normal but PET or SPECT scans are abnormal, then there is a 50%–60% likelihood of excellent surgical outcome. If all imaging studies are normal, surgical benefit drops to 25%–30%. **Hemispherectomy** (removing the damage or diseased hemisphere of the brain) is performed for hemimegalencephaly and Rasmussen encephalitis, and occasionally for porencephaly with widespread focal cortical dysplasia.

Palliative Surgery When a seizure focus cannot be identified, or cannot be safely removed surgically due to involvement of eloquent cortex, or when there are multiple seizure foci, then palliative epilepsy surgery may reduce seizure frequency or severity. These procedures rarely result in seizure freedom but may improve quality of life. Disconnecting the corpus callosum (the thick band of nerves connecting the right and left hemispheres of the brain; see Chapter 8) by means of a corpus callosotomy is a treatment option for refractory epilepsy, including atonic (or drop) seizures and secondarily generalized epilepsy (Rosenfeld & Roberts, 2009).

Neuromodulatory Therapies The vagal nerve stimulator provides an intermittent electrical impulse to the left vagus nerve. Approximately 40% of selected individuals may have a 50% reduction in targeted seizures (Mapstone, 2008).

As of 2018, deep brain stimulation and responsive cortical stimulation to abort seizures in response to cortical detection of seizures are being studied in adults but are not yet available for testing in children (Jobst, Darcey, Thadani, & Roberty, 2010).

Nonspecific Interventions Common factors that provoke or exacerbate seizures include sleep deprivation and infections with or without fever. Parents and children should be counseled about good sleep hygiene and the importance of prevention and treatment of infections and fever. Flashing lights provoke seizures in children with photosensitive epilepsy and so should be avoided. Seizures may also be exacerbated around the time of ovulation or menses. Poor adherence to taking ASMs is an important cause of breakthrough seizures, and compliance issues should be discussed with the family.

Vitamins, Minerals, and Complementary and Alternative Medicine Folate supplementation is recommended for females who are taking valproate during their child-bearing years. Pyridoxine (vitamin B₆) is indicated in the treatment of a rare form of epilepsy resulting from pyridoxine dependency or deficiency.

Calcium and vitamin D supplementation may be helpful in preventing osteoporosis. Seizures associated with certain inborn errors of metabolism may be treated with vitamins and nutritional supplements.

There is considerable interest from families of children with medically intractable epilepsy about the value of medical marijuana in the treatment of refractory epilepsy. There are limited data indicating improvement in seizure control with cannabidiol (a drug similar, but not identical, to tetrahydrocannabinol, the active substance in medical marijuana) in some epilepsy syndromes. In a recent randomized controlled trial in individuals with Dravet syndrome (a complex epilepsy syndrome and epileptic encephalopathy that presents during the first year of life, cannabidiol resulted in a higher rate of significant seizure reduction as compared to placebo. Adverse effects were mild to moderate and included vomiting, diarrhea, fever, fatigue, somnolence, and abnormal liver function tests (Devinsky et al., 2017). Abnormal liver function tests also tend to be seen in individuals concomitantly taking valproate.

Cannabidiol inhibits or induces the hepatic cytochrome enzyme system, resulting in alteration in blood levels of various medications metabolized by the liver, including ASMs (Brodie & Ben-Menachem, 2017). The interaction between clobazam and cannabidiol is well documented. The blood level of clobazam and its metabolite (N-desmethyloclobazam) increase significantly in individuals taking cannabidiol, resulting in excessive sedation. Hence, close monitoring for side effects, drug level monitoring, and adjusting the doses of drugs may be required while on cannabidiol. Although some families consider alternative medicine for the treatment of epilepsy, there is no evidence that the various homeopathic and herbal remedies are effective (Danesi & Adekunji, 1994). It is important to understand that “natural” is not necessarily harmless (see Chapter 39).

MULTIDISCIPLINARY CARE

Addressing the various needs of a child with epilepsy requires a multidisciplinary approach, preferably in a comprehensive epilepsy center. The team includes neurologists, psychiatrists, neuropsychologists, nurses, social workers, and other health professionals.

School Performance and Educational Programs

Children with epilepsy may have cognitive and learning difficulties. A child with absence seizures may start to do poorly as seizure frequency increases. Dosage change or introduction of a new ASM may cause

decreased attention and somnolence, which may interfere with the child's school performance. Irritability and aggression may occur as a result of medication adverse effects. Comorbidities such as ADHD may coexist with epilepsy and contribute to poor school performance. Teachers need to be aware of the need for closer monitoring of school performance in children with epilepsy. A child with declining school performance needs a thorough evaluation for possible causes including seizure exacerbation, ASM adverse effects, comorbidities (e.g., ADHD and depression), learning and memory problems, and psychosocial stress. Also, the educational program should be reviewed. Corrective actions may include medication adjustment, treating comorbidities, and designing an individualized education program. Children with epilepsy are eligible to receive special education and related services through the Individuals with Disabilities Education Improvement Act of 2004 (PL 108-446) under the educational classification of "other health impairment" (see Chapter 33).

Having a seizure in the classroom may be a source of anxiety and embarrassment, especially for a child who has tonic-clonic convulsions associated with bladder or bowel incontinence. Educating classmates about epilepsy and what to expect may be helpful. Parents may request a classroom discussion about seizures. The discussion does not have to identify the specific child (Coleman & Fielder, 1999). By contrast, if a child's epilepsy is well controlled and daytime seizures do not occur, a discussion about seizures with classmates may be counterproductive, as the child will be identified as different and subjected to potential stigmatization. For children with poorly controlled seizures associated with incontinence, a towel and fresh change of clothing can be kept in the nurse's office.

Psychosocial Issues

Epilepsy affects health-related quality of life (HRQL) measures through several mechanisms: 1) frequency of seizures, 2) ASM adverse effects, 3) comorbidities (e.g., anxiety, depression, and learning disorders), 4) the presence of an underlying neurologic disorder, 5) social stigma, and 6) the unpredictability of seizures. Even children who have had only a single seizure or children newly diagnosed with epilepsy are more likely to report impaired HRQL, perhaps as a consequence of child and parental anxiety (Modi et al., 2009). Social stigma may affect the child's self-perception, leading to low self-esteem and depression. Parents may react to seizures by overprotecting their child, which may have the unintended consequence of fostering lifelong

dependence. Seizures affect the entire family. Mothers of children with epilepsy tend to be at increased risk for depression (Ferro & Speechley, 2009). There also is a significant financial and time burden to the family. The child as well as the whole family needs to be educated about epilepsy and support should be provided.

Children with epilepsy should generally be encouraged to participate in sports. Routine safety precautions should be applied as with any child. However, some sport activities pose a specific danger to the life of a person with epilepsy (e.g., scuba diving, rock climbing, parachuting, and unsupervised swimming) and should be avoided (Fountain & May, 2003).

Family vacations and camping trips should be encouraged, but excess fatigue should be avoided. The family needs to have an adequate supply of ASMs, and the doctor's and pharmacy's contact information should be on hand. Wearing a medical identification bracelet or necklace may be useful if it is acceptable to parents and the child.

Independence should be encouraged as the child enters adulthood. Driving license laws vary from state to state, but generally the individual needs to be seizure free for between 3–12 months before their license can be obtained or reinstated. An altered fertility rate and potential teratogenic effects of ASMs are issues that need to be addressed.

Several organizations advocate and provide resources for individuals with epilepsy, including the American Epilepsy Society, the Epilepsy Foundation, and the International League Against Epilepsy.

OUTCOME

A majority of children (70%–80%) with epilepsy achieve seizure control with the first or second ASM, and about two thirds can be successfully weaned off their ASMs after 2 years of being seizure free (MacDonald et al., 2000). Children with "idiopathic" epilepsy have better long-term outcomes than those with "cryptogenic" epilepsy, who in turn have better long-term outcomes than those with remote symptomatic epilepsy (Sillanpää et al., 2015).

Children who have had a single seizure have comparable intelligence scores to siblings (Sogawa, Masur, O'Dell, Moshe, & Shinnar, 2010). In one prospective study, approximately 74% of children with epilepsy had typical global cognitive function, while the remaining 26% had lower cognitive functioning. Young age at seizure onset, symptomatic cause, epileptic encephalopathy, and continued need for ASM treatment were significant independent risk factors for cognitive impairment (Berg et al., 2008).

The most common causes of mortality in epilepsy are 1) an accident (most often swimming related), 2) the underlying cause of the epilepsy (e.g., brain tumor), and 3) sudden unexpected death in epilepsy (SUDEP). SUDEP is an underappreciated cause of seizure-related deaths (Sillanpää & Shinnar, 2010), and it may be related to post-ictal alterations in respiratory and cardiac function (Harden et al., 2017; Ryvlin et al., 2013). Accurate data on the incidence of SUDEP are lacking. A meta-analysis of studies suggests an incidence of 0.22 out of 1,000 patient-years in childhood, which makes it a very rare occurrence (Harden et al., 2017). Generalized tonic-clonic seizures and nocturnal seizures appear to be risk factors for SUDEP. Other factors that increase the risk of SUDEP include early childhood onset of epilepsy, developmental delay, and refractoriness to multiple ASMs (Morse & Kothare, 2016). Children with Dravet syndrome are also at increased risk of SUDEP (Shmueli, Sisodiya, Gunning, Sander, & Thijs, 2016).

Continued seizures, medication side effects, and depression are associated with poor outcomes, including reduced quality of life, undereducation, unemployment, failure to achieve independence, and difficulties establishing lifelong social bonds (Sillanpää, 2000).

SUMMARY

- Epilepsy is characterized by recurrent seizures that result from abnormal electrical discharges in the brain.
- A seizure is classified as generalized or focal, depending on whether it involves both hemispheres at onset or starts in one hemisphere with or without subsequent spread to the other hemisphere.
- Most epilepsy can be controlled with a single ASM, but there are other treatment options.
- For children with epilepsy associated with multiple disabilities or symptomatic causes, the prognosis is more related to the disabilities and underlying causes than to the epilepsy itself.
- Side effects of medications and comorbidities should be assessed in conjunction with seizure control to optimize quality of life.

CHAPTER 23

Acquired Brain Injury

Sarah Risen, Scott C. Schultz, and Melissa K. Trovato

Upon completion of this chapter, the reader will

- Describe the different etiologies of acquired brain injury (ABI)
- Explain the incidence, common etiologies, and clinical course of mild, moderate, and severe traumatic brain injury (TBI) in children
- Discuss the management of mild TBI, specifically return-to-learn and return-to-play plans
- Identify clinical features concerning abusive head trauma and describe the subsequent evaluation of this condition
- Understand the nontraumatic causes of ABI
- Understand the key elements of rehabilitation and the outcomes associated with ABI
- Identify the most important strategies for ABI prevention
- Explain why a comprehensive, interdisciplinary team is essential to the acute and long-term care of children with acquired brain injury

Acquired brain injury (ABI) is a nonprogressive insult to the brain after birth resulting in acute, and often chronic, disruption of neurological function. Traumatic brain injury (TBI) is the most common cause of ABI in children, and abusive head trauma (AHT) is the most common cause in infants and toddlers. TBI is classified as mild, moderate, or severe and has a wide spectrum of injury outcomes. Other mechanisms of ABI include anoxic/hypoxic-ischemic brain injury (e.g., cardiac arrest, asphyxiation, and submersion), stroke, infectious (encephalitis/meningitis), autoimmune encephalitis, and other causes.

For all etiologies of ABI, it is important to understand that brain injury in children occurs in the context of a developing brain and therefore can disrupt underlying neurodevelopmental processes by both primary and secondary injury. The clinical symptoms and related management of ABI are generally divided into acute, subacute, and chronic periods. Symptoms at initial presentation may reflect focal regions and/or more diffuse areas of brain dysfunction. Associated symptoms vary by etiology.

Depending on the cause and extent of brain injury, children with ABI may be at risk for

long-term impairments or changes in the sensory systems (i.e., vision or hearing), physical function, cognition, language, behavioral and emotional regulation, personality, endocrine function, and sleep regulation. These impairments and changes can adversely affect a child's function at home, in school, and in the community; therefore, a comprehensive multidisciplinary team approach is essential to identify problems and provide strategies to optimize the child's ability to participate in all environments.

■ ■ ■ CASE STUDY

Johnny was a previously healthy 9-year-old boy who presented to the emergency department (ED) with dizziness and sleepiness after hitting his head on the ground when he fell from play equipment at school. His parents were told by school personnel that he cried immediately (i.e., there was no reported loss of consciousness), but Johnny does not remember climbing on the equipment or the fall. The school nurse noted he seemed confused, and she called his parents, who then brought him to the local hospital.

In the ED, Johnny remained confused and began to have episodes of vomiting. The ED physician ordered a computed tomography (CT) scan of the head given his persistent altered mental status during observation in the ED and onset of emesis. The head CT showed no evidence of skull fracture or internal hemorrhage. His symptoms began to improve after several hours, and he was discharged home with a diagnosis of concussion and recommendations for strict rest (a common recommendation *not* based on up-to-date concussion management evidence, as discussed below) until follow-up evaluation by his primary care physician (PCP).

His parents brought him for follow-up appointments with his PCP several times over the following 3 weeks; she then referred Johnny to the multidisciplinary concussion clinic because of persistent postconcussive symptoms (i.e., daily headache, dizziness, increased sleep, and irritability). Of note, while he had not attempted school work during this time, his parents were concerned that he was not thinking as clearly as before the fall. Four weeks following his concussion, Johnny was seen by the pediatric neurologist, neuropsychologist, and behavior psychologist in a multidisciplinary concussion clinic. At that time, he exhibited the same symptoms; in addition, his parents were concerned that his irritability and behavior were beginning to worsen. He had not been cleared to return to school because his parents were told to wait "until all symptoms resolve" before sending him back or allowing him to return to his normal activities.

On reviewing Johnny's current daily schedule, the team noted that he was sleeping late, eating sporadically,

and "resting all day," although his parents noted that lately it has been incredibly challenging to keep him from running around. They felt they were constantly telling him to stop doing things to ensure that he could heal. They shared that Johnny was "bored" at home and wanted to get back to playing baseball. A 45-minute targeted neuropsychological battery revealed overall average to high average cognitive function in most areas but mild weakness in processing speed and working memory.

Johnny and his parents were counseled on concussion and the expected course of recovery. He was provided an individualized return-to-school plan, and lifestyle interventions were emphasized, specifically hydration, regular meals, adequate and consistent sleep (melatonin was recommended for sleep initiation), and avoidance of headache medication overuse. Johnny was taught strategies for activity pacing and developed a daily schedule alternating work, breaks, and preferred activities. Although returning to school full time was emphasized, the benefits of slowly increasing levels of aerobic exercise were also discussed as long as the degree of exertion did not increase concussive symptoms. The team modified a "return-to-play" plan, allowing activity up to (but not beyond) high-aerobic, noncontact activity.

At clinic follow-up 2 weeks later, Johnny and his parents noted a significant reduction in his symptoms, especially his headaches and irritability. He was attending school full days but with accommodations. He was tolerating high-intensity aerobic sports drills without symptoms, and repeat neuropsychological testing revealed improvement in the prior areas of weakness. School accommodations were gradually removed, and he was able to complete all make-up work before his final clinic visit 3 weeks later. At that time (9 weeks following his initial injury), he was asymptomatic, functioning in school without any additional support, and cleared to complete the final stages of the return-to-play plan. Johnny was able to play in the final tournament of his baseball season.

■ ■ ■ CASE STUDY

Paul is a previously healthy 9-year-old boy who was a belted backseat passenger involved in a motor vehicle collision. The vehicle was hit on the driver's side by a tractor trailer while traveling on the highway. Upon arrival, emergency medical services noted that Paul was unresponsive, and his Glasgow Coma Scale (GCS) score (a quantitative scale to describe a person's level of consciousness) was a 3, the lowest possible score reflecting severe neurological impairment. He was intubated and transported via helicopter to the nearest trauma center.

At the trauma center, a head CT showed a right frontal skull fracture with underlying hemorrhage. He emergently went to the operating room for intracranial

pressure (ICP) monitor placement and was admitted to the intensive care unit (ICU). The ICU followed the recommended management guidelines for children with severe TBI. He initially required medications to maintain an adequate blood pressure but then developed intermittent hypertension, tachycardia (elevated heart rate), and hyperthermia (elevated temperature) consistent with paroxysmal sympathetic hyperactivity. While in the ICU, Paul had persistent significantly impaired level of consciousness, requiring a tracheostomy and gastrostomy tube placement 2 weeks after injury. He had increased muscle tone and was seen several days per week by physical and occupational therapy for range of motion exercises and other services.

When Paul became medically stable, he was transferred to the neurology unit for ongoing care. As sedating medications were weaned, he became more responsive. Magnetic resonance imaging (MRI) of his brain completed 4 weeks after injury revealed a large intracranial hematoma in the right frontal lobe and corpus callosum, as well as punctate hemorrhages scattered throughout the left occipital lobe, left frontal lobe, and brainstem, reflecting diffuse axonal injury (DAI).

Paul was then transferred to an inpatient rehabilitation unit. At that time, Paul had spontaneous eye opening and intermittent eye opening to verbal stimuli. After 16 weeks, Paul was inconsistently following simple commands and inconsistently answering yes/no questions with a head nod/shake. Spontaneous movements of his extremities were noted, on the right greater than the left. Paul was discharged from inpatient rehabilitation 24 weeks post injury. He required a ventilator to assist with nighttime breathing due to central sleep apnea and was dependent on a gastrostomy tube for all nutrition.

Paul was then admitted to a day rehabilitation program, where he received intensive physical, occupational, and speech therapy services. At 28 weeks following injury, Paul continued to be in a posttraumatic amnesia (PTA) state (i.e., he was having difficulty learning new information, but he was consistently following commands and able to make choices using eye gaze or reaching with his right hand).

Over the next 6 months, Paul continued to make slow, steady gains, although his cognitive and language functioning remained significantly impaired compared with age-matched peers. He was able to communicate his basic wants and needs with cues, move all his extremities, and walk using a walker and bilateral forearm platforms for 200 feet with minimal assistance. Paul required the use of bilateral ankle-foot orthoses to maintain foot position and provide stability. He was able to feed himself with supervision and required minimal assistance for grooming, bathing, and dressing skills.

Paul underwent a modified barium swallow test and was cleared for intake of a regular diet with nectar-thickened liquids. The gastrostomy tube began to be used only for liquid supplementation.

Paul was then transitioned to school with the support of an individualized education program (IEP), developed with the help of an educator from the day program in coordination with the school system. At school, he continued to receive therapy services as well as outpatient physical, occupational, and speech therapy. At 1 year post injury, he continued to make slow progress in all domains.

Thought Questions:

What can parents and teachers do to educate children about the consequences of traumatic brain injury? What can parents and teachers do to assist in the prevention of traumatic head injury in children?

OVERVIEW OF TRAUMATIC BRAIN INJURY

This section provides an overview of TBI, including incidence, causes, pathophysiology (primary and secondary injuries), and initial evaluation.

Incidence

In 2013, approximately 2.8 million Americans sustained a TBI. This represented an increase from 1.6 million in 2007 accounted for by a surge in mild TBI (mTBI)-related ED visits (Taylor, Bell, Breiding, & Xu, 2017). Children younger than 15 years of age sustain an estimated 661,000 TBIs each year, with nearly 1,500 TBI-related deaths occurring in this population. It is important to note that these numbers only account for children with brain injury seen in an ED. As many children may be seen by their pediatrician or a subspecialty provider rather than in the ER, the number of children sustaining at least mild TBIs each year is likely even higher than reported.

Motor vehicle accidents, falls (e.g., from playground equipment), sports injuries (especially football, lacrosse, and hockey), recreational activities (e.g., skiing and surfing), and assault are the common causes of TBI. The precipitants of TBI tend to vary with age. In children younger than 1 year of age, abusive head trauma is the most likely etiology, occurring at a rate of 39.8 per 100,000 children in the United States (Niederkröthaler, Xu, Parks, & Sugerman, 2013). The most frequent overall mechanism of injury in children 0–4 and 5–14 years of age is unintentional falls (which includes unknown intent), whereas motor vehicle collisions are most common in adolescents and young

adults 15–24 years (Taylor et al., 2017). Figure 23.1 presents the causes of TBI by age group and percentage.

Pathophysiology: Primary and Secondary Injury

TBI results from a direct or indirect biomechanical force exerted on the brain, which is a soft and deformable organ within the rigid skull. Primary brain injury occurs at the moment of impact and can include 1) brain contusions (a localized bruise of brain tissue), 2) vascular injuries causing hemorrhage (bleeding within the brain), 3) skull fractures, and 4) diffuse axonal injury (DAI) (shearing of the nerves that send information between different areas of the brain). A neurometabolic cascade is also triggered at the moment of impact, including widespread release of glutamate (an excitatory neurotransmitter in the brain that can cause injury at high levels), ionic changes, and metabolic alterations. TBI also results in impaired cerebral blood flow and glucose metabolism (Giza & Hovda, 2014). These changes continue to evolve over days and contribute to additional (secondary) brain injury.

Secondary brain injury refers to the cascade of events that occurs in the brain hours to days after the primary injury, resulting in further tissue damage. Secondary injuries include 1) brain swelling/edema, 2) increased intracranial pressure, 3) ischemia or infarctions (diffuse or focal loss of oxygen to the brain or clot related strokes), 4) seizures, 5) alterations in cerebral blood flow, 6) ongoing axonal injury, 7) ongoing metabolic related toxic injury (leading to brain cell death), 8) reduced glucose metabolism, and 9) impaired mitochondrial function (which normally provides energy for brain cells). Additional systemic alterations, such as elevated body temperature, hyperglycemia or hypoglycemia, or hypotension (low blood pressure), have been associated with poorer outcomes, likely compounding the effects of secondary brain injury (Natale, Joseph, Helfaer, & Shaffner, 2000; Vavilala et al., 2003; Young et al., 2017).

Initial Evaluation

Of children presenting to EDs with head trauma, most injuries are mild (upwards of 90%) and do not require acute medical or surgical intervention (Faul, Xu, Wald, & Coronado, 2010). If a child hits his or her head and remains awake, alert, conversant, interactive, and otherwise asymptomatic, close observation and monitoring at home are sufficient. However, a more comprehensive evaluation at an ED is necessary if any of the following signs or symptoms occur:

Figure 23.1. Causes of traumatic brain injury by age and percentage. (From Taylor, C. A., Bell, J. M., Breiding, M. J., & Xu, L. [2017]. Traumatic Brain Injury-Related Emergency Department Visits, Hospitalizations, and Deaths—United States, 2007 and 2013. *MMWR Surveill Summ*, 66[9], 1–16.)

- Any loss of consciousness
- A change in mental status (e.g., difficulty speaking, seizures, confusion, lethargy, excessive sleepiness, or extreme irritability)
- Weakness in the arms or legs
- Complaints of severe headaches that do not abate
- Complaints of changes in hearing or vision
- Nausea and projectile vomiting

In the ED, a neurological examination will be performed. Given the risks of exposure to radiation, it is important to understand that a head CT is not required in the evaluation or diagnosis of concussion in children. Based on the published Pediatric Emergency Care Applied Research Network guidelines for identifying children at risk for concerning injury following head trauma, the ED physician may or may not decide to obtain a head CT (Kupperman et al., 2009). A head CT aids in the evaluation of more severe injury such as bleeding in or around the brain and skull fractures, but it does *not* “diagnose” concussion. In more severe brain injuries, brain MRI provides higher resolution images and is much more effective than CT scans in determining the presence and extent of DAI and other injuries (see Chapter 8). Depending on the clinical progression, results of the physical examination and neuroimaging studies, the child may be discharged home with close observation and follow-up or admitted to the hospital for further care. Children with severe TBIs should be transferred to the nearest Level 1 pediatric trauma center following acute stabilization.

SEVERITY OF TRAUMATIC BRAIN INJURY

There are two common ways to categorize the severity of TBI: the Glasgow Coma Scale (GCS) (Teasdale, 2014; Teasdale & Jennett, 1974) and the duration of post-traumatic amnesia (PTA). The GCS assesses motor response (scored from 1–6), verbal response (1–5), and eye opening (14) within the first 24 hours after brain injury. Following acute resuscitation, if needed, a GCS score of 8 or lower indicates a severe TBI; scores 9–12 indicate a moderate TBI; and scores 13–15 indicate a mild traumatic brain injury. In the acute setting, a person with a score below 8 is said to be comatose (Chung et al., 2006). While a worse outcome across developmental domains is associated with more severe brain injury (and thus a lower GCS score), it is important to note that the prognostic ability of the GCS is limited in children with TBI, and a child with a GCS score of 3–5 can still have meaningful recovery with functional independence (Catroppa, Godfrey, Rosenfeld, Hearps,

& Anderson, 2012; Emami et al., 2017; Lieh-Lai et al., 1992).

The duration of posttraumatic amnesia is the length of time for a child to remember events and store new memories. The Children’s Orientation and Amnesia Test (Ewing-Cobbs, Levin, Fletcher, Minor, & Eisenberg, 1990) is a widely used tool to assess PTA. In mild TBI the duration of PTA is less than 1 hour, in moderate TBI the duration is between 1 hour and 1 day, and in severe TBI the duration of PTA is longer than 1 day (Wilson, Teasdale, Hadley, Wiedmann, & Lang, 1994). Length of PTA as well as time to follow commands have been shown to be the most consistent and reliable, though weak, predictors of long-term outcome (Davis, Slomine, Salorio, & Suskauer, 2016).

Mild TBI (Concussion)

The term *concussion* (which is an mTBI) continues to receive a significant amount of media attention, especially as it relates to professional football players. In 2013, a little more than 1 million children (from birth to 24 years) were seen in U.S. EDs for brain injury (Taylor et al., 2017). Accounting for children seen by pediatricians, athletic trainers, or other providers, another resource estimates that there are between 1.6 and 3.8 million sports-related concussions (SRCs) in the United States each year (Langlois, Rutland-Brown, & Wald, 2006). Although sports injury is a common and frequently highlighted cause of mTBI, there are many other potential causes, especially falls (e.g., from playground equipment or bicycles), that are actually more common in children less than 12 years of age.

Children seem to be uniquely susceptible to potentially fatal consequences of a second TBI occurring during the acute phase of recovery from an initial concussion, a phenomenon referred to as second impact syndrome (McCrory, Davis, & Makdissi, 2012; McLendon, Kralik, Grayson, & Golomb, 2016). There are now specific laws in all 50 states to protect children by 1) requiring immediate removal of any athlete suspected of having sustained a concussion from participation in sports and 2) prohibiting the child’s return to sports until cleared by a qualified professional. The specifics of each law vary by state, but most contain these two components as well as a mandate to educate coaches and/or parents about concussion prior to the start of the season. The application of the laws also vary, with some applicable only to public school athletes and some including community recreational teams.

Diagnosis The most recent Consensus Statement on Concussion in Sport defines SRC as “a traumatic brain injury induced by biomechanical forces.”

(McCrory et al., 2017, p. 839). Several common features that may be utilized in clinically defining the nature of a concussive head injury include the following:

- SRC may be caused either by a direct blow to the head, face, neck, or elsewhere on the body with an impulsive force transmitted to the head.
- SRC typically results in the rapid onset of short-lived impairment of neurological function that resolves spontaneously. However, in some cases, signs and symptoms evolve over a number of minutes to hours.
- SRC may result in neuropathological changes, but the acute clinical signs and symptoms largely reflect a functional disturbance rather than a structural injury, and, as such, no abnormality is seen on standard structural neuroimaging studies.
- SRC results in a range of clinical signs and symptoms that may or may not involve loss of consciousness. Resolution of the clinical and cognitive features typically follows a sequential course. However, in some cases symptoms may be prolonged.

The clinical signs and symptoms of SRC cannot be explained by drug, alcohol, or medication use; other injuries (such as cervical injuries, peripheral vestibular dysfunction, etc.); or other comorbidities (e.g., psychological factors or coexisting medical conditions; McCrory et al., 2017).

As illustrated by Johnny in the chapter's initial case study, symptoms of a concussion are typically divided into four overall categories and include (but are not limited to) 1) physical manifestations (confusion, headache, nausea, vomiting, dizziness, hypersensitivity to lights [photophobia] or sounds [phonophobia], loss of balance, and blurry or double vision), 2) changes in sleep (increased or decreased ability to sleep and fatigue), 3) change in emotions/behavior (irritability, increased sadness or nervousness, and increased emotional lability), and 4) changes in cognitive function (difficulty with concentration or memory and responding more slowly than normal). Younger children or those with developmental disabilities may be less likely to express these specific symptoms, and therefore clinical signs (such as increased clinginess, enuresis, appetite changes, nightmares, or other behavior changes) should be considered as proxies for postconcussive symptoms.

There are several validated concussion-related assessments that can be used both on the sideline (for sports-related injuries) and in a clinical setting. The most recent Consensus Statement on Concussion in Sport recommends using the Sports Concussion Assessment Tool, Fifth Edition (SCAT5 and Child SCAT5) as a validated and well-established multimodal concussion assessment tool (Davis et al., 2017).

Management Children with concussion should be evaluated at regular intervals (initially about every 2 weeks) until clinical recovery. This can be done by a provider in one of several disciplines: pediatrics, sports medicine, neurology, or physical medicine and rehabilitation. At each evaluation, ongoing clinical symptoms are assessed. Neither computerized testing nor a neuropsychological evaluation is required in the evaluation of a child with an uncomplicated concussion. A neuropsychologist may complete an assessment focused on functions commonly affected by mTBI. This can provide useful information on the course of cognitive recovery, which may differ from clinical symptom resolution.

Research on mTBI does not support the need for complete rest beyond the acute period following concussion, generally 48 hours (Thomas, Apps, Hoffmann, McCrea, & Hammeke, 2015). There is evidence that supports the avoidance of significant overexertion (i.e., returning immediately to full/nearly full levels of cognitive and physical activity) during the early stages of recovery (i.e., the first few days; Brown et al., 2014). The clinical management of a child with concussion needs to be individualized based on the child's specific symptoms, school and sports circumstances, and response to treatment recommendations. Academic, athletic, and recreational activity management plans need to be modified at each visit based on the child's current status.

After 1–2 days of rest (or at least reduced activity level), a child should transition back to school with appropriate accommodations provided. As concussive symptoms in children can persist for an average of 1–2 months, it is not feasible, and in fact may be harmful, to wait until complete symptom resolution prior to returning to school. Therefore, it is essential for providers to be familiar with common school adjustments and academic accommodations that can optimize a child's return to school and recovery from injury (Box 23.1). The American Academy of Pediatrics (AAP) has published a thorough report on "Returning to Learning" that can help guide a provider who is managing a child after a concussion (Halstead et al., 2013). In addition, the Centers for Disease Control (CDC) Acute Concussion Evaluation (ACE) care plan is accessible online and includes common academic accommodations for providers to modify/recommend in the "Returning to School" section (CDC, 2015).

Just as a stepwise increase in academic activity is recommended, a gradual increase in physical exertion (below a level causing worsening/increase in symptoms) is also advised. For athletes, there are several specific "return-to-play" protocols that providers can access (such as the one outlined in the CDC ACE care plan). For children who are not involved in a formal

BOX 23.1 EVIDENCE-BASED PRACTICE**Returning to School and to Sports Following Concussion/Mild Traumatic Brain Injury (mTBI)**

Each year, there are between 1.6 and 3.8 million sports-related concussions in the United States (Langlois, Rutland-Brown, & Wald, 2006). Providers, educators, coaches, and athletic trainers are faced with important decisions regarding when a child should return to school or sports and how to implement an optimal plan to resume these activities.

Return to Learning

In a survey of high school nurses, only half of schools had a plan in place to support the return of a child to school following a concussion, and only two thirds of school nurses had training in concussion (Olympia, Ritter, Brady, & Bramley, 2016). Primary care providers may also be unaware of the needed supports for a child with concussion returning school. In a chart review of primary care providers' initial evaluations of children diagnosed with concussion, only 28% of the pediatricians provided the child/family with return-to-school instructions and only 11% provide recommendations for cognitive rest (Arbogast et al., 2013).

The American Academy of Pediatrics has published "Returning to Learning Guidelines" to assist providers in the development of instructions for schools to optimize the transition back to school for children with concussion (Halstead et al., 2013).

Return to Play

A child who has sustained a concussion should not be "cleared" to return to contact sports before being able to tolerate full days of school without accommodations. (As noted in this chapter, some degree of aerobic activity may enhance concussion recovery, so carefully prescribed noncontact exercise may be permitted prior to full recovery based upon the provider's clinical evaluation and judgment.) Once a provider with expertise in concussion has determined that a child is ready to be cleared to resume sports, the return-to-play protocol guides the child's gradual return to contact sports. However, in a chart review of primary care providers' initial and follow-up evaluations of children diagnosed with concussion, only about 50% of pediatricians provided return-to-activity instructions (Arbogast et al., 2013). Furthermore, one study found that only 15%–40% of high school athletes complied with these return-to-play guidelines, with the athletes that did *not* follow the guidelines returning to contact sports before recommended (Yard & Cornstock, 2009).

Several "return-to-play" guidelines have been published, with all protocols gradually increasing non-contact aerobic exertion prior to returning to contact practice, followed by competitive play (May et al., 2014; McCrory et al., 2012).

Application to Practice

As with other aspects of concussion management, return to play protocols should be individualized, with considerations including the age of the athlete, history of prior concussions, and the specific sport to which they are returning (Canty & Nilan, 2015).

athletics program, it is still recommended to gradually increase physical exertion as tolerated and avoid contact or high-risk activities that could result in another mTBI until the current concussion has fully resolved.

Children with concussion should be symptom-free and able to complete all schoolwork without accommodations (and at preinjury levels of performance) prior to being allowed to return to unrestricted activities, especially contact sports. The decision to allow a return to normal activities may be challenging in the small portion of children with persistent postconcussive symptoms. Children with an atypical or prolonged clinical

course, who are unable to tolerate increased cognitive or physical demands despite appropriate accommodations, should be referred to a multidisciplinary clinic with expertise in brain injury for ongoing clinical assessment and management.

Clinical Course Symptom resolution and clinical recovery is expected within 1–2 months in children with concussion (Corwin et al., 2014; Risen, Reesman, Yenokyan, Slomine, & Suskauer, 2017), although a small portion of children report persistent symptoms and require referral to a provider with expertise in

brain injury (Barlow et al., 2010; Keenan & Bratton, 2006; Sroufe et al., 2010). Literature supports the strong contribution of premorbid child and family psychological factors to persistent postconcussive symptoms, which may respond well to cognitive behavioral intervention (Bernard, Ponsford, McKinlay, McKenzie, & Krieser, 2016; McNally et al., 2018). This emphasizes the importance of a multidisciplinary treatment team in this population.

Moderate to Severe TBI

In 2013, nearly 50,000 children were admitted to the hospital secondary to TBI and nearly 8,000 children sustained a fatal TBI (Taylor et al., 2017). Though less frequent than mild injuries, moderate and severe TBI are associated with significant and persistent impact on the child and family (Babikian, Merkley, Savage, Giza, & Levin, 2015; Rashid et al., 2014).

Diagnosis Similar to mTBI, moderate to severe TBI results from a biomechanical force transmitted directly or indirectly to the brain; however, children with moderate to severe TBI present with more pronounced neurological deficits (see above for GCS and PTA injury severity classification criteria). As illustrated by Paul, in the second case study at the beginning of this chapter, diagnosis and treatment of moderate to severe TBI begins at the scene of injury or in the ED. After assessment and stabilization of a child's breathing and circulation, a more extensive evaluation of the brain and spine will occur. As noted, the postresuscitation GCS score will help determine the initial severity of brain injury and may guide ongoing acute management. The Brain Trauma Foundation has published guidelines on the acute medical management of severe TBI in children (Kochanek et al., 2012), and adherence to these recommendations has been shown to be associated with improved survival and outcome at discharge from the hospital (O'Lynn et al., 2016; Vavilala et al., 2014). Throughout a child's hospital course, the goal of treatment is to prevent or limit secondary brain injury.

CT scans of the head and neck, to assess the extent of brain injury and for possible cervical spinal injury, are typically obtained acutely. Children with more severe brain injuries may require a neurosurgical procedure, such as placement of a device to measure ICP. An MRI may be obtained once the child is stabilized to provide further information on the extent of brain damage.

Seizures may occur after a TBI and can increase neurometabolic demand, worsening secondary brain injury. Seizures after TBI are categorized based on the postinjury timing in which they occur. Impact-related seizures are defined as those that occur at the time of

injury, usually within minutes of sustaining a TBI (most often an mTBI) but typically do not reflect an increased risk for a long-term seizure disorder (Arndt, Goodkin, & Giza, 2016). Early posttraumatic seizures (EPTS) include immediate posttraumatic seizures (within 24 hours) and delayed EPTS (within the first week following injury; Arndt et al., 2016); they are more common than impact seizures. EPTS have been related to an increased risk for late posttraumatic seizures (Arango et al., 2012) and poorer outcome (Arndt et al., 2013). In children with moderate to severe TBI who undergo continuous electroencephalogram (EEG) monitoring (see Chapter 22), EPTS occurs in roughly 30%, with nearly half having only subclinical seizures (seizure activity detected on EEG but without clinical signs in the child; O'Neil et al., 2015). EPTS are more common in severe TBI, especially with intracranial hemorrhage or depressed skull fractures, abusive head trauma, and in children less than 3 years of age (Arango et al., 2012; Arndt et al., 2016; Bennett, DeWitt, Harlaar, & Bennett, 2017; Liesemer, Bratton, Zebrack, Brockmeyer, & Statler, 2011).

Late posttraumatic seizures (LPTS) occur after the first week of injury and present with greater frequency in older children and young adults (Statler, 2006); however, epileptic spasms have been reported in infants 2 months–2 years following severe TBI (Park & Chugani, 2017). Risk factors for LPTS include abnormal head CT with skull fractures and bleeding in the brain and early posttraumatic seizures (Emanuelson & Uvebrant, 2009; Park & Chugani, 2015). Anti-epileptic prophylaxis (treating with a medication to prevent seizures) has been shown to prevent EPTS but not LPTS (Chang, Lowenstein, & Quality Standards Subcommittee of the American Academy of Neurology, 2003). The risk for ongoing posttraumatic seizures is greatest within the first year following injury but persists even 10 years following TBI, especially in those children with severe TBI (Annegers & Coan, 2000; Christensen et al., 2009). Furthermore, children with severe TBI and posttraumatic epilepsy may be more likely to have intractable epilepsy and be on multiple anti-epileptic medications (Park & Chugani, 2015).

Management Throughout the hospitalization period, efforts should be made to prevent the complications of prolonged bedrest. These problems may include decreased muscle mass and strength, bone loss, skin breakdown, loss of range of motion at joints (contractures), and weight loss. Contractures and skin breakdown may be prevented by appropriate positioning and frequent repositioning. Passive range of motion should be undertaken once the child is medically stable.

Nutrition plays an important role following TBI because of increased daily calorie and protein needs during the healing process (Vavilala, Kernic, et al., 2014; Vavilala, Lujan, et al., 2017). The child may require an alternative means of nutrition, such as a nasogastric tube, to receive calories, liquids, and medication. Gastroesophageal reflux and decreased rate of stomach emptying may also be a problem. Urinary and bowel incontinence is common after severe brain injury, but there may also be urinary retention and constipation, which should be appropriately treated.

Paroxysmal sympathetic hyperactivity (PSH; also known as dysautonomia, diencephalic or thalamic seizures, autonomic or sympathetic storming) occurs in approximately 10% of children with moderate to severe TBI within days to weeks of injury (Kirk et al., 2012; Deepika, Mathew, Kumar, Devi, & Shukla, 2015) and is associated with increased mortality and worse rehabilitation outcomes (Kirk et al., 2012; Pozzi et al., 2014). PSH reflects severe dysregulation of the sympathetic nervous system (SNS) caused by dysfunction of the thalamus or hypothalamus or their connections within the brain (Blackman, Patrick, Buck, & Rust, 2004; see Chapter 8). The diagnosis is based on presence of otherwise unexplained SNS symptoms, including elevated temperature, tachycardia, tachypnea (rapid breathing), hypertension, sweating, and dystonic posturing (abnormal positioning of limbs). PSH typically requires management with medications such as benzodiazepines, beta-blockers like propranolol, or alpha2 agonists like clonidine (Kirk et al., 2012; see Chapter 38).

Clinical Course Following severe TBI, recovery is most rapid during the first year and slows during the following year (Gorman, Barnes, Swank, & Ewing-Cobbs, 2017; Taylor et al., 1999). Recovery is influenced not only by the severity of injury, but also by family factors, including socioeconomic status, resources, and support systems (Anderson, Spencer-Smith, et al., 2009; Catroppa et al., 2012; Keenan & Bratton, 2006). In addition, variability in the rate of recovery and the effects on differing neurodevelopmental domains in children who sustain TBI at different ages suggest an age-dependent neuro-pathophysiological influence on the rate of recovery and neurodevelopmental outcome (Babikian et al., 2015). For many years, it was believed that the younger the age of injury, the better the outcome due to the plasticity of the brain. However, it has been shown that children who sustain a brain injury at an *earlier age* (infants and toddlers) are at increased risk for lasting impairments across all areas compared with older children who sustain a brain injury (Anderson et al., 2009; Andruszkow et al., 2014; Crowe, Catroppa,

Babl Rosenfeld, & Anderson, 2012). Yet, stage of development at the time of injury also has an impact on outcome, with differing domains more or less vulnerable at different periods of development. A child may return to the previous developmental level following injury but may have trouble progressing past that stage (Babikian et al., 2015; Giza, Kolb, Harris, Asarnow, & Prins, 2009). This difficulty with progressing into new developmental levels or attaining new developmental milestones has been described as a neurocognitive stall (Babikian et al., 2015; Chapman, 2007). This may be noted in all age groups and is typically manifest as a slowing or lack of further progression in the intellectual, motor, and social development of the child 1 year after injury. Beyond this period of cognitive stall, children will continue to gain skills, though likely at a slower developmental rate.

The outcomes for children who have sustained moderate to severe TBI are variable. Persistent and significant impairments are associated with more severe primary injury, more frequent secondary injuries, a longer ICU stay, and a longer hospital stay (Anderson & Catroppa, 2006; Campbell, Kuehn, Richards, Ventureyra, & Hutchison, 2004). Areas typically affected include language, working memory, executive function, and speed of information processing (Anderson & Catroppa, 2006; Babikian et al., 2015; Campbell et al., 2004). Even with these impairments, a child's preinjury academic skills and global intelligence may remain intact; it is new learning that is most impaired (Babikian et al., 2015). Social, emotional, behavioral, and sleep problems are also common following pediatric TBI and can have a significant impact on a child's daily function.

Abusive Head Trauma

Abusive head trauma (AHT; termed shaken baby syndrome, inflicted head injury, or nonaccidental trauma) is a severe TBI inflicted via abrupt forceful impact and/or violent shaking of infants or young children. Children with AHT most often present emergently with nonspecific signs, such as irritability, vomiting, lethargy, trouble feeding, and apnea (stopping breathing); they may also present with more specific neurological symptoms such as seizures.

AHT is a serious public health concern. In the United States, AHT occurs in 30 to 50 per 100,000 children less than 5 years of age, with the highest rate in children less than 1 year of age (Boop, Axente, Weatherford, & Klimo, 2016; Shanahan, Zolotor, Parrish, Barr, & Runyan, 2013). Importantly, an infant or child who has sustained even a minor abusive injury is at increased risk for future, more severe abuse, including AHT. In a study of infants diagnosed with AHT, nearly

one third were previously seen by providers in settings where abuse could have been identified. They often had presented in the past with emesis or bruising or having had prior child protective services (CPS) contact (Letson et al., 2016).

Diagnosis The classic features of AHT are subdural hematoma (SDH; bleeding between the skull and the brain) and retinal hemorrhages (RH; bleeding into the eye seen by an ophthalmologist when examining the back of the eye). As AHT may be inflicted on a child in many different ways (e.g., shaking, blunt force trauma, suffocation, strangulation), these features or other signs of physical injury are not required for the diagnosis of AHT. The diagnosis of AHT is based on the history, physical exam, and medical evaluation. It is essential for providers to recognize all possible red flags of AHT.

In cases of AHT, the cause of injury reported by caregivers is often inconsistent with the clinical findings and the severity of brain injury sustained. For example, although many studies support the benign nature of a fall from a low height (3–4 feet) such as a couch or bed (Lyons & Oates, 1993; Levene & Bonfield, 1991), in a study of infants with traumatic intracranial hemorrhage, children reported by parents to have fallen from a height of less than 3 feet actually had evidence of *more* severe brain injuries (with an increased incidence of SDH, RH, and seizures) and had worse outcomes than those reported by parents to have suffered a variety of other causes. Infants whose parents reported not knowing the mechanism of injury had the *most* severe injuries and outcomes (Amagasa, Matsui, Tsuji, Moriya, & Kinoshita, 2016). The implication is that there would be a higher suspicion of abuse when parents cannot report the mechanism of injury or when the reported mechanism of injury is insufficient to explain the severity of the injury itself. Changes in the history provided by the caregiver upon additional questioning, varying accounts from several caregivers, and other signs of physical abuse (e.g., bruising or patterned marks, such as handprints from slapping, linear marks from an object such as a belt, circular lesions from cigarette burns, etc.) should also raise suspicion for AHT. The hospital's child protective team, which has expertise specifically in the evaluation and diagnosis of abusive injuries in children, should be involved as soon as abuse is suspected.

Management Once the suspicion is raised for AHT by the history, exam, or head CT (i.e., finding SDH), a complete evaluation should be done, including 1) an ophthalmological evaluation looking for RH, 2) a skeletal survey/x-rays for evidence of fractures

indicating physical abuse, 3) brain MRI and cervical spine imaging, 4) involvement of the hospital's child protective team, and 5) notification of CPS. If resources allow, continuous EEG monitoring is recommended given the increased frequency of both clinical and subclinical seizures and status epilepticus (persistent seizure activity). Additional laboratory investigation is based on clinical judgment.

While SDH is a cardinal feature of AHT, other intracranial hemorrhages and skull fractures may occur, resulting from direct impact, as well as DAI. Considering the great force needed to inflict AHT and the mechanism of injury, the cervical spinal cord is also vulnerable, especially in ligamentous injury (Choudhary, Ishak, Zacharia, & Dias, 2014), and both AHT and cervical spinal cord injury are associated with bilateral hypoxic-ischemic (reduced oxygen and blood flow delivery) brain injury (Kadom et al., 2014).

Clinical Course AHT has a high mortality rate and is also a major cause of morbidity in young children. In fact, given the unique differences in the infant and young child's nervous system and the major neurodevelopmental changes that occur throughout the first years of life, infants and very young children appear to be particularly vulnerable to effects of brain injury, especially with regard to cognitive development (Anderson, Spencer-Smith et al., 2009). Furthermore, secondary brain injuries, (including seizures, increased ICP, and stroke) are more common in AHT compared with accidental TBI (Ferguson et al., 2017; Hymel, Makoroff, Laskey, Conaway, & Blackman, 2007; Risen, Suskauer, Dematt, Slomine, & Salorio, 2014). The presence of increased morbidity and secondary injuries in AHT emphasizes the importance of strict adherence to the severe TBI guidelines and the use of aggressive neuroprotective strategies (treatment strategies designed to reduce secondary injury) in this population. In addition, children with AHT make similar functional gains during inpatient rehabilitation and following discharge as do children with nonabusive (accidental) head trauma, underscoring the need to ensure ongoing rehabilitation services (Risen et al., 2014).

NONTRAUMATIC ACQUIRED BRAIN INJURY

Common types of nontraumatic ABIs include anoxic/hypoxic-ischemic brain injury, pediatric stroke, infectious encephalitis/meningitis, autoimmune encephalitis, and other causes of ABI (radiation, toxins, etc.). Given the multiple etiologies, it is difficult to determine the overall incidence of ABI in children. While the

pathophysiology is unique to each individual cause, the acute disruption in neurological function and potential for chronic neurological impairment are the common bond within ABIs.

Anoxic/Hypoxic-Ischemic Brain Injury

Anoxic (absence of oxygen delivery) and hypoxic-ischemic brain injury are a common cause of ABI encompassing several etiologies, including cardiac arrest (most commonly secondary to respiratory failure in children), submersion (drowning), and asphyxiation (hanging). See Chapter 5 for a discussion of neonatal hypoxic-ischemic encephalopathy.

Hypoxic-ischemic brain injury due to cardiac arrest is most often as a consequence of respiratory failure in children. While certainly less common than in the adult population, it is difficult to determine the overall incidence and epidemiology of nonfatal cardiac arrests in the general pediatric population. Specific populations, such as those with congenital heart disease or certain arrhythmia syndromes, are at high risk for cardiac-mediated arrest. Cardiac arrest may occur in a hospital setting (e.g., in an ED or ICU) or in a community setting; outcomes differ depending on where the event occurs (see below).

Drowning is the most common cause of accidental death in children 1–4 years of age and one of the top five causes of unintentional death in children overall (Borse et al., 2008; Laosse, Gilchrist, & Rudd 2012). Nonfatal drownings occur in approximately 10 of every 100,000 children in the United States, with the highest rate (16 out of every 100,000) in children ages 0–4 years (Felton, Myers, Liu, & Davis, 2015). The highest rates of nonfatal drowning occur in swimming pools (although natural waterways, including freshwater ponds, lakes and streams, and oceans, and bathtubs are other common locations) and among children from minority populations, especially African Americans (Felton et al., 2015).

Asphyxiation/strangulation brain injuries may be intentional (self-inflicted) or unintentional (accidental suffocation). Sadly, hanging/strangulation is the most common mechanism of suicide in school-age children and is especially prevalent among black males with ADHD and young adolescents with depression (Sheftall et al., 2016). Sudden infant death syndrome (also referred to as “sudden unexpected death in infancy”) and accidental suffocation during sleep are common causes of hypoxic-ischemic injury and death in infants. Suffocation is 20 to 40 times more likely to occur among infants who sleep in an adult bed than among those who sleep in a crib; by contrast, the risk of suffocation is reduced in infants who sleep in the *same room* (but not the *same bed*) as an adult caregiver (Moon

& Task Force on Sudden Infant Death Syndrome, 2016; Scheers, Rutherford, & Kemp, 2003). The importance of prevention efforts for both intentional and unintentional asphyxiation injuries are discussed below.

Independent of etiology, anoxia/hypoxia and ischemia trigger a deleterious neurometabolic cascade, starting with depletion of brain energy reserves and followed by accumulation of harmful metabolites that ultimately trigger neuroinflammation and neuronal cell death. Brain MRI reveals different patterns of hypoxic-ischemic injury depending on the severity of the insult and age (i.e., brain maturity; Huang & Castillo, 2008; White, Zhang, Helvey, & Omojola, 2013). Neuroimaging of milder hypoxic injury in children typically involves the watershed zones and subcortical white matter. Severe hypoxia in postneonatal infants and children up to 2 years of age results in diffuse injury to the gray matter. In contrast to the pattern seen in neonatal injury (see Chapter 5), brain MRI of children 1–2 years of age with hypoxic-ischemic injury may have sparing of the perirolandic cortex and thalami (see Chapter 8). In older children (typically older than 2 years of age), severe hypoxic-ischemic injury imaging patterns appear similar to adults, with vulnerability of the deep gray nuclei, cortex, hippocampi, and cerebellum. Although findings on MRI do not consistently relate to neurological function (Christophe et al., 2002), neuroimaging abnormalities demonstrating diffuse hypoxic-ischemic injury suggest the potential impact on a wide range of neurological functions.

Similar to TBI, it is important to minimize secondary brain injury following anoxia/hypoxia. Continuous EEG monitoring should be considered in children with anoxic/hypoxic-ischemic injury given the increased risk for clinical and subclinical seizures in this population. Furthermore, during the subacute period, children with anoxic/hypoxic-ischemic brain injury are more likely than children with TBI to experience paroxysmal sympathetic hyperactivity. Although there is no specific treatment strategy for anoxic brain injury, a comprehensive, systematic approach similar to TBI is more likely to mitigate further neurological injury.

Although there is a large breadth of literature evaluating neurological outcomes following pediatric TBI, fewer studies have reported outcomes following anoxic/hypoxic-ischemic injury. As of 2018, available studies draw upon samples from inpatient pediatric rehabilitation facilities, which typically reflect the most severely impaired children and do not likely represent the full spectrum of outcomes.

Hypoxic-ischemic brain injury due to cardiac arrest, as mentioned above, is most often a consequence of respiratory failure in children. Although in-hospital cardiac arrest is typically associated with higher survival

than out-of-hospital cardiac arrest, the neurological outcomes for both have improved over time. Several factors, including cardiac etiology, bystander performance of cardiopulmonary resuscitation (CPR), duration of CPR, and time to epinephrine administration to restart the heart, have been associated with improved neurological outcome (Anderson et al., 2015; Del Castillo et al., 2014; Forrest, Butt, & Namachivavam, 2017).

Neuropsychological evaluations of children with anoxic brain injury and drowning do suggest a broad spectrum of long-term neurological deficits, including poor coordination and fine motor movements, mild to severe cognitive deficits, and behavioral difficulties (Suominen, Sutinen, Valle, Olkkola, & Lönnqvist, 2014; Thaler et al., 2013). Children with anoxic/hypoxic-ischemic brain injury, however, certainly have the potential to benefit from rehabilitation (discussed later) and to make significant functional gains following hospital discharge.

Pediatric Stroke

Pediatric stroke is another important cause of ABI associated with neurodevelopmental morbidity. Reports on the incidence of stroke from birth to 18 years of age ranges from 1 to 13 per 100,000 children per year (Felling, Sun, Maxwell, Goldenberg, & Bernard, 2017; Roach et al., 2008). Stroke can be categorized as arterial ischemic stroke (loss of blood flow in arteries supplying the brain), venous stroke (secondary to a clot in the brain's venous system), or hemorrhagic stroke (bleeding into the brain substance, ventricles, or subarachnoid space of the brain). In children, stroke can be further categorized by age at the time of stroke, and these categories are associated with different risk factors, presentation, and outcomes.

Perinatal stroke is defined as a stroke that occurs from the prenatal period to 29 days after birth and has unique risk factors related to maternal/pregnancy variables. Any stroke that occurs after 29 days of life is termed childhood stroke. Childhood stroke is also different from strokes in adults, having different risk factors, causes, types, recurrence risk, and outcomes. Unlike adults, a group of risk factors that are not related to lifestyle may predispose children to stroke, including 1) congenital or acquired cardiac disease, 2) prothrombotic states (conditions associated with an increased risk of blood clots), 3) sickle cell disease (see Chapter 24), 4) genetic and metabolic disorders, and 5) cerebral arteriopathies (abnormal development of the arteries of the brain). Almost one half of children with stroke have a known risk factor, and in a systematic review of childhood strokes, nearly one third of ischemic and hemorrhagic strokes

had an undetermined cause (Gumer, Del Vecchio, & Aronoff, 2014).

Perinatal stroke may present acutely in the neonatal period with seizures, or present months later (between 4–6 months of age) when asymmetric motor development (weakness on one side of the body) is first recognized. Childhood arterial ischemic stroke may present with the acute onset of focal deficits consistent with the function of the brain region having lost perfusion. Common symptoms include 1) unilateral hemiparesis (weakness) of the face and arm (with or without leg weakness), 2) language or speech difficulties, and 3) ataxia (difficulties with balance); however, they may also include seizures, headache, altered mental status, or a reduced level of awareness. Venous thrombosis is more likely to present with a more gradual onset of diffuse symptoms such as headache, nausea, and vomiting. Acute onset of severe headache typically signals hemorrhagic stroke, which may also be associated with seizures, reduced awareness, and focal signs related to the area of hemorrhage and surrounding edema.

Management of childhood stroke is extrapolated from the literature on the management of adult stroke given the paucity of pediatric stroke treatment trials other than for sickle cell disease (for which intravenous hydration and exchange transfusion are recommended; see Chapter 24). However, while the overarching goal in adult stroke care is rapid diagnosis and management, there is commonly a delay in the diagnosis of stroke in children, and there are questions regarding the optimal treatment of pediatric stroke (see Jordan & Hillis, 2011, and Kirton & deVeber, 2015 for comprehensive reviews on the challenges unique to management of pediatric stroke). Several consensus statements and guidelines review the management of childhood stroke. The American Heart Association guidelines provide recommendations in the management of neonatal and childhood ischemic and hemorrhagic stroke and include recommendations for specific etiologies of stroke (Roach et al., 2008).

The risk of stroke recurrence varies by etiology, most often occurring within the first year following the initial stroke. The overall risk for recurrence of childhood arterial ischemic stroke within 1 year is approximately 7%, but it is significantly increased if cerebral arteriopathy is the underlying etiology. For example, up to 32% of individuals with Moyamoya disease, a progressive cerebral arterial disorder, have recurrent strokes (Fullerton et al., 2016).

Neurodevelopmental sequelae are common, occurring in up to 80% of children with stroke. Motor deficits are the most common and pronounced initial findings, but cognitive, sensory, and emotional/behavioral

impairments may emerge over time, reflecting more extensive disruption in neurological function. Gross and fine motor deficits can greatly affect a child's ability to perform daily activities. The trajectory of gross and fine motor recovery following childhood stroke is affected by the age of the child at injury and size of the stroke, with poorer 5-year outcomes in children sustaining arterial ischemic stroke between 1 month and 5 years of age as well as larger and/or bilateral strokes (Cooper et al., 2017; Cooper et al., 2018). Premorbid conditions, often related to the stroke, also affect outcome following stroke. These include children with congenital heart disease and Down syndrome, who may have neurodevelopmental deficits independent of, and then compounded by, a stroke.

Infectious Encephalitis/Meningitis

Infectious encephalitis (inflammation of the brain tissue) and meningitis (inflammation in the membranes surrounding the brain) are broad categories of disease with great variability in age of onset, presenting symptoms, clinical course, laboratory and radiological features, and outcome. More than 100 viruses have been associated with infection of the brain or spinal cord, although herpesviruses, arboviruses (tick or mosquito born), and enteroviruses are the most common. The introduction of vaccinations has changed the nature of bacterial meningitis. While vaccinations have reduced the incidence of *Haemophilus influenzae* type b meningitis by 97% and *Streptococcus pneumoniae* (pneumococcal) meningitis by 34%–62%, there has been a concomitant increase in pneumococcal meningitis caused by serotypes not covered by the vaccine (Kowalsky & Jaffe, 2013). Brain injury due to CNS infection is a consequence of direct invasion of brain tissue by infectious agents, and the subsequent neuroinflammatory response has the potential to induce further brain injury.

Children may present with active infectious symptoms (such as fever, respiratory or gastrointestinal symptoms, and decreased feeding) and neurological symptoms that vary by age of child and etiology (examples include altered mental status, irritability, stiff neck, and seizures). The International Encephalitis Consortium has outlined the definition and diagnostic algorithms for encephalitis, including clinical, laboratory, and imaging features suggestive of specific infections in children (Venkatesan et al., 2013). Evaluation for CNS infection includes a thorough history, physical exam, serum and cerebrospinal fluid (CSF) laboratory studies, and brain MRI. Given the multitude of variables that affect the differential diagnoses in a child presenting with central nervous system infection (such as age,

region, and exposure), a pediatric infectious disease provider is often involved in the child's evaluation and treatment decisions. Even with extensive testing, however, the specific infectious cause may not be identified, particularly in presumed viral encephalitis.

The outcome depends on a variety of factors including the child (the "host") and the specific infectious organism (virus or bacterium). Neurodevelopmental sequelae are common following CNS infections and, similar to other mechanisms of ABI, may emerge over time as the child develops. In a meta-analysis of infectious encephalitis in children, Khandaker and colleagues (2016) have reported that long-term neurodevelopmental sequela (i.e., cognitive dysfunction, behavioral abnormalities, and neurological disorders) occur in one half of the affected population, although the outcome varies by etiology with some infections, such as neonatal herpes simplex virus, having the worst outcome. Similarly, at least one half of children with bacterial meningitis have long-term neurodevelopmental disabilities, primarily intellectual and behavioral, and hearing loss is reported in 7%–14% of these children, with 5% having profound hearing loss (Chandran, Herbert, Misurski, & Santosham, 2011; Rodenburg-Volt, Ruytjens, Oostenbrink, Goedegebure, & van der Schroeff, 2016).

Brain injury rehabilitation, early assessment, and long-term neurodevelopmental monitoring is warranted for children following infectious encephalitis and meningitis. In addition, early audiological testing is recommended following bacterial meningitis, with follow-up testing based on clinical symptoms as post-meningitic hearing impairment can improve or worsen over time.

Autoimmune Encephalitis

Autoimmune encephalitis occurs when the body's own immune system mistakenly targets brain tissue, resulting in inflammation and potential brain injury. Acute-disseminating encephalomyelitis (ADEM) is an immune-mediated CNS demyelinating disorder that typically follows a systemic infection by days to weeks. The body's immune system, in an attempt to react to infection, mistakenly targets the tissues of the CNS, especially the white matter (myelin) that insulates nerve cell processes. Encephalopathy (altered mental status) is required for the diagnosis. Other features of ADEM may include focal neurological deficits and seizures as well as a characteristic pattern on brain MRI; however, there are no specific blood or CSF tests for ADEM.

Anti-NMDA receptor encephalitis is the second most common cause of autoimmune encephalitis and is a potentially devastating autoimmune neurological disorder affecting children and young adults. The

classical presentation of anti-NMDA receptor encephalitis, described in adults, involves acute behavioral change and psychiatric symptoms followed by seizures, memory deficits, movement disorder, and vital sign lability (Titulaer et al., 2013). However, less is known about the presentation of anti-NMDA receptor encephalitis in children, especially young children. A review of case reports of children less than 3 years of age with anti-NMDA receptor encephalitis suggests that this youngest cohort typically presents with behavioral changes, movement disorders, and speech arrest (Goldberg, Titulaer, de Blank, Sievert, & Ryan, 2014). Therefore, autoimmune encephalitis should be considered in the differential diagnosis of a child presenting with loss of developmental skills (developmental regression).

Across all ages, earlier treatment with immune-modulating therapies is thought to be related to better outcome, and with continued symptom improvement for 12–24 months (Byrne et al., 2015). Bigi, Hladik, Twilt, Dalmau, and Benseler (2015) have provided a comprehensive review of the current known pediatric antibody-associated inflammatory disorders: anti-NMDA receptor encephalitis, Hashimoto encephalitis (also known as steroid-responsive encephalopathy), aquaporin-4, and anti-GAD-65 encephalitis. They note that 27% of affected individuals have ongoing and functionally impairing neurological deficits 2 years following diagnosis. Similar to other etiologies of ABI, these inflammatory brain processes may occur at various stages of neurodevelopment and have the potential to affect ongoing development. As deficits may emerge over time, long-term neurodevelopmental monitoring is recommended in children following autoimmune encephalitis.

Other Causes

Autoimmune disorders (such as systemic lupus erythematosus) may have CNS involvement, sometimes even presenting with neurological or neuropsychiatric symptoms. Toxins (such as chemotherapy and carbon monoxide) and radiation therapy also can induce diffuse brain injury and have long-term neurodevelopmental sequelae (see Chapters 2 and 25). Emerging evidence indicates that refractory status epilepticus or persistent seizure activity that does not respond to typical aggressive seizure management (i.e., febrile infection-related epilepsy syndrome and new-onset refractory status epilepticus) triggers a deleterious autoinflammatory response of the immune system in the brain, contributing to both the development of epilepsy and brain injury (Kenney-Jung et al., 2016).

As with any cause of ABI, children with these conditions who experience prolonged hospitalization

or severe functional deficits should have intensive inpatient or outpatient brain injury rehabilitation. The potential neurodevelopmental consequences of such diffuse brain injury processes are high and emphasize the importance of vigilant long-term neurodevelopmental monitoring.

REHABILITATION AND OUTCOMES

Once a child with ABI is medically stable and ready for the next level of care, he or she may be transitioned to a rehabilitation hospital for intensive inpatient therapy or may participate in outpatient rehabilitative therapy services depending on the severity of the child's functional impairments. A rehabilitation facility should have the following components of care: 1) expertise in rehabilitation of children, 2) developmentally appropriate treatments, 3) family-centered care, and 4) attention to the child's education and reintegration into the school system. Many rehabilitation hospitals are accredited through the Commission on Accreditation of Rehabilitation Facilities, which sets standards of care for the facilities and offers specialty accreditations for brain injury programs and pediatric specialty programs.

As the child recovers from ABI, functional impairments may become apparent in the following domains: motor (gross and/or fine motor control and balance), sensory (vision or hearing), feeding skills, communication (speech and language), cognition (memory and processing), and behavior (Savage, DePompei, Tyler, & Lash, 2005).

Rehabilitation strives to 1) prevent complications that are caused by immobilization and disuse, 2) increase the use of abilities regained, 3) teach strategies to compensate for impaired or lost function, and 4) alleviate the effect of chronic disability on the process of growth and development (Cope, 1995). The primary goals of rehabilitation for all impairments related to ABI include promotion of recovery, compensation for impairments, and identification and treatment of cognitive and behavioral issues.

Following ABI, the medical team and/or primary care provider help determine the level of care needed. A multidisciplinary intervention including physical therapy, occupational therapy, speech therapy, neuropsychology, special education, and social work may be necessary depending on the severity of the injury and impairments.

Motor Impairments

Motor recovery and functional prognosis following ABI are typically of concern. Studies have shown that motor weakness tends to improve over time and

that functional outcomes are good. In TBI, prognosis of motor recovery is related to duration of coma, and significant motor recovery may occur in children who are comatose for less than 3 months (Brink, Imbus, & Woo-Sam, 1980). Evaluating nearly 500 children with ABI admitted to inpatient rehabilitation, 70% regained mobility (7.6 months after injury on average) and functional self-care and mobility skills continued to improve over 5 years following injury (Beretta, Molteni, Galbiati, Stefanoni, & Strazzer, 2017).

Persistent impairments may be noted in strength, balance, speed, and coordination (Beretta et al., 2017), and assessment of hand function reveals decreased fine motor skills, speed, and coordination (Kuhz-Buschbeck et al., 2003). Constraint-induced movement therapy (i.e., therapy that employs inhibition or constraint of the unaffected limb to encourage use of the impaired limb) is a specific rehabilitation program beneficial for children with unilateral hemiparesis (of any etiology), resulting in positive functional gains in the weaker limb (DeLuca, Trucks, Wallace, & Ramey, 2017).

Motor recovery is also affected by motor impairments related to movement patterns and tone, such as spasticity, dystonia, tremor, and ataxia. Medications or surgery may be used to treat some of these impairments. Medications to treat spasticity and dystonia include baclofen, dantrolene, diazepam, trihexiphenadyl, and tizanidine (see Appendix C). Baclofen may be given orally or directly into the spinal fluid with an intrathecal baclofen pump (Albright & Ferson, 2006). Management of spasticity may also involve localized neuromuscular blockade with botulinum toxins or nerve blocks, such as phenol injections. The effects of botulinum toxins last several months, but repeated injections may be required (Bjornson et al., 2007; Clemenzi et al., 2012; Meholic-Fetahovic, 2007). Injections should be followed by physical or occupational therapy services to obtain the desired results. Tremor may be treated with propranolol (Inderol) or carbidopa/levodopa (Sinemet). There is, as of 2018, no medicine or surgery that is effective for ataxia.

Orthopedic surgery may be necessary for the treatment of contractures and bony orthopedic deformities. Surgeries may include tendon lengthening, femoral osteotomies (reconfiguring the femur to treat hip spasticity), or spinal fusion for scoliosis.

Sensory Impairments

Both vision and hearing may be affected following ABI. Visual impairments can be due to injury of the optic nerves, impaired visual processing in the brain, or limitation of eye movements resulting from cranial nerve damage. Double vision is common following ABI

because of cranial nerve injury. Other impairments may include nystagmus (shaking eye movements caused by cerebellar damage), decreased visual acuity, difficulty with tracking, and visual field cuts. Traumatic injury to the optic nerve is not reversible and can cause blindness (Bodack, 2010; Cockerman et al., 2009). Injury to the occipital lobes, leading to visual cortex damage, can cause cortical blindness (the ability to see but not process visual information; see Chapter 25). Vision assessment by an ophthalmologist or neuro-ophthalmologist is recommended for evaluation of the above impairments.

Sensorineural hearing loss or conductive hearing loss can occur following ABI (especially bacterial meningitis) and is generally unilateral. Hearing loss may be a result of trauma to the middle (conductive) or inner (sensorineural) ear due to traumatic skull base fractures or damage to the central neuronal pathways. Sensorineural loss is more pronounced at the higher hearing frequencies (Lew, Jerger, Guillory, & Henry, 2007; Munjal, Panda, & Pathak, 2010). Given these concerns, audiological evaluation is recommended following ABI. Brainstem auditory-evoked responses can be used for testing children who are unable to participate in traditional behavioral audiometric testing (Lew et al., 2004; see Chapter 26).

Feeding Disorders

ABI can cause **dysphagia** (difficulty in swallowing), which affects oral nutrition and hydration. It can also have a negative impact on a child's ability to protect the airway, leading to an increased risk of aspiration pneumonia (see Chapter 29). The incidence of dysphagia following ABI overall is low; however, it increases markedly with increasing severity of injury. For instance, the incidence of acute dysphagia associated with severe TBI is 68%–76% (Morgan, 2010; Morgan, Mageandran, & Mei, 2010). Associated impairments include atypical tongue movements, poor jaw stability, inefficient chewing, impaired lip closure, and reduced attention and impulsivity during feeding. Signs of aspiration can include coughing after swallowing, wet voice after swallowing, and delayed swallow initiation (Morgan et al., 2010).

A child with dysphagia may require a feeding tube to provide nutrition and hydration. The tube may be a temporary measure, such as a nasogastric tube, or a long-term option, such as a percutaneous (placed through the skin without opening the abdomen) endoscopic gastrostomy (PEG) tube. Children with a PEG tube will receive a standard concentration enteral formula (e.g., Pediasure) to attain maximum nutrition with minimum volume (Cook, Peppard, & Magnuson, 2008).

Given the importance of nutrition on brain injury recovery and ongoing rehabilitation, it is critical to ensure the most optimal method of feeding for a child with ABI.

Communication Skills and Language Impairments

A variety of speech, language, and communication skills can be affected by ABI. Dysarthria (a dysfunction in the motor control of the muscles used for speech that affects articulation and intelligibility) is an especially important sequelae of ABI. The incidence of dysarthria for TBI in children specifically ranges from 2%–60% (Cahill et al., 2005; Morgan et al., 2010). As mentioned above, motor impairment and dysphagia are significantly associated with dysarthria (Morgan et al., 2010).

Language impairments may be expressive (relating to the ability to express thoughts in words and sentences) or receptive (relating to the ability to process and understand language) (see Chapter 17). While basic aspects of speech production (articulation, vocabulary, and grammar) may remain intact following TBI, more complex (“higher-order”) language skills and processing are often impaired in children and adolescents with ABI. Daily conversation and real-life, complex communication skills are impaired in children following ABI (Fyrberg, Horneman, Asberg Johnels, Thunberg, & Ahlsen, 2017). The more complex features of language processing are affected by cognitive deficits involving difficulty with judgment related to topic management, turn taking, and pause time (Fyrberg, Marchioni, & Emanuelson, 2007). Individuals with TBI are less appropriate in their use of language and style of speech and have difficulty initiating and sustaining a conversation (Dahlberg et al., 2007). These language and processing deficits often impair a child’s social interactions and are related to externalizing (challenging) behaviors (Catroppa & Anderson, 2004). Social isolation may result from these communication impairments.

Language development may be particularly vulnerable to ABI during early childhood. Children who sustained moderate to severe TBI between 4–6 years of age were found to have more significantly impaired verbal abilities and language skills compared with mTBI and children without TBI (Crowe et al., 2014). Speech and language assessment is an important aspect of ongoing neurodevelopmental monitoring following ABI.

Cognitive Impairments

Cognitive impairments are common following ABI. Areas affected may include attention, memory, executive function (planning, initiating, and problem

solving), and speed of processing (Babikian et al., 2015; Dikmen et al., 2009). Long-term outcome is correlated with injury severity. The more severe the injury sustained, the worse the outcome across all cognitive domains. Environmental factors unrelated to the injury also have an impact on outcome, including parental occupation, preinjury adaptive abilities, age at time of injury, and preinjury behavior (Anderson et al., 2004).

Preschool children with severe TBI demonstrate slower recovery with poorer cognitive outcome up to 5 years after injury compared with children less severely injured (Anderson et al., 2009; Ylvisaker & Feeney, 2007). Children who are younger at the time of injury may not show the full extent of their cognitive impairments until they reach school age, when the task complexity increases (Anderson & Catroppa, 2005; Babikian et al., 2015; Meekes, Jennekens-Schinkel, & van Schooneveld, 2006).

Cognitive impairments are identified through evaluation by a neuropsychologist that includes tests and questionnaires to assess cognitive, emotional/behavioral, and adaptive functioning (see Chapter 13). The assessment is typically performed in a quiet setting with minimal distractions, and it can be completed while a child is in the hospital or rehabilitation setting or on an outpatient basis. It involves a set of standardized measures to assess language, visuospatial skills, concept formation, reasoning, problem solving, attention, memory, and academic performance. Questionnaires and interviews to assess adaptive and social/emotional functioning are also undertaken.

The results of this testing can be used to assess cognitive strengths and weaknesses (including deficits attributable to ABI effects) and to assist in treatment planning, including educational placement, accommodations, or adjunct therapies (e.g., speech-language therapy, cognitive rehabilitation, executive functioning coaching, and psychotherapy) as necessary (Ylvisaker et al., 2005). Repeat neuropsychological evaluation is recommended as the child reintegrates into the school and community. As the child ages and demands are increased, cognitive impairments may become more apparent and warrant repeat testing and monitoring.

Behavior, Socialization, and Family

Following TBI, changes may be noted in a child’s behavioral, emotional, and social interactions. These changes may include adjustment difficulties, psychiatric disorders (including depression and anxiety), disinhibition (lack of restraint manifested as inappropriate social behavior, impulsivity, and poor risk assessment), and social withdrawal (Anderson & Catroppa, 2006; Ylvisaker et al., 2005). Preinjury behavioral and family

functioning is also correlated to postinjury function (Anderson et al., 2001).

Management may include medications, counseling, and/or behavioral reinforcement, all of which are tailored to the child's needs (Anderson & Catroppa, 2006; Bates, 2006; Riggio & Wong, 2009; Ylvisaker et al., 2005; see Chapter 27). Behavioral issues and social withdrawal can lead to tension within the family, and social isolation not only affects the child, but can also lead to isolation of the entire family (Kapapa et al., 2010).

Caregivers of children with a severe TBI are also under greater stress and are at higher risk for psychological symptoms (Aitken et al., 2005; Gan & Schuller, 2002). Coping strategies used by families may include denial and disengagement (Stancin, Wade, Walz, Yeates, & Taylor, 2008). Parents and siblings may feel guilt and remorse after the injury. Mothers and fathers often have different coping styles, which may further exacerbate family dysfunction (Wade et al., 2010; see Chapter 37). Prolonged hospitalization may additionally place a financial burden on the family and affect the overall finances and dynamics of the family. Therefore, family support is important in all phases following a TBI, during the acute hospitalization, rehabilitation, and school reintegration. Social workers, psychologists, educators, and other health care professionals may work with the family to assist with resources, family coping and adjustment, discharge planning, and school reentry. Ongoing support groups in the community may be recommended and utilized (Aitken et al., 2005).

School Reentry

One of the main goals following rehabilitation is school and community reintegration. Sustaining an ABI places a child at risk for the presence of long-term academic difficulties, especially following more severe injury. Reading and math abilities may be compromised as well as attention, concentration, and memory (Catroppa et al., 2009; Hawley, Ward, Magnay, & Mychalkiw, 2004). Educational testing as well as neuropsychological testing should be completed to obtain a comprehensive view of the child's impairments (see Chapter 13). Long-term follow-up studies of school-age children with TBI reveal impairments that persist or worsen as the children progress through school (Babikian et al., 2015; Glang et al., 2008).

Special education support is available to those who qualify under one or more of the eligibility categories of the Individuals with Disabilities Education Improvement Act (IDEA) of 2004 (Box 23.2 describes the role of the educational specialist in remediating TBI). TBI is one of the IDEA eligibility categories, and individuals with nontraumatic ABI may qualify under Other

Health Impaired. Eligibility in most states requires medical documentation of a TBI or ABI, and physical and intellectual assessments must show a difference between preinjury and postinjury performance. It should be noted that preinjury functioning can be determined by interview and record review.

When a student qualifies, an individualized education program (IEP) is created by a team of individuals, including the parents and representatives from the school or school district (see Chapter 33). The IEP outlines direct services and accommodations needed for the student to be successful in the school environment. Examples include therapy services provided by the school system; a range of classroom settings from self-contained to assistance in the classroom; focused instruction; organizational support; and increased time or strategies to address impairments in attention, organization, or memory. When a child needs accommodations but not direct services, he or she may qualify to receive support and accommodations with a Section 504 plan (Rehabilitation Act of 1973, PL 93-112). These can include reduced work, extended time, check-ins regarding assignments and deadlines, and other organizational supports.

Obtaining an IEP or a Section 504 plan is an important aspect of school reintegration. Without a plan in place, educators may not recognize the impairments and needs of the student. During their training, teachers are rarely exposed to children with ABI; thus, they may not be aware of the potential effects of ABI on learning, memory, and behavior (Glang et al., 2008; Hawley et al., 2004). An IEP or Section 504 plan allows for communication across all school settings regarding the injury and resultant impairments (Hawley et al., 2004). Children with TBI who receive transition support from the hospital are more likely to have an IEP or Section 504 plan in place. Planning for school reentry, transition support, and education of school staff, as well as long-term monitoring, are all important for successful reintegration and school placement.

PREVENTION

Many types of unintentional traumatic injuries are preventable. The leading causes of nonfatal injuries in children are falls; poisoning; burns; and motor vehicle, bicycle, and pedestrian accidents (CDC, 2010). Falls are more common in younger children, bicycle and pedestrian collisions are more common in elementary and middle school-age children, and motor vehicle collisions are more common in adolescents (Mendelson & Fallat, 2007). For each of these brain injury etiologies, there are available prevention strategies. For example, the use of window guards and gates at stairways and

BOX 23.2 INTERDISCIPLINARY CARE**The Education Specialist and Moderate to Severe Traumatic Brain Injury (TBI)**

Despite the fact the TBI is known to be associated with neurocognitive sequelae that affect educational outcomes and that the diagnosis of TBI can qualify a child for special education services, schools and teachers are often unprepared to support the needs of children returning to school following moderate to severe TBI (Linden, Braiden, & Miller, 2013).

Not all children with TBI will require special education services, but a significant percentage of children with moderate to severe TBI have some combination of cognitive, learning, language, motor, social, and behavioral difficulties that can impact their ability to learn and perform in school. Children with TBI who are admitted to rehabilitation programs often undergo neuropsychological and educational assessment to evaluate learning strengths and weaknesses and to help guide necessary educational supports as the child returns to school. The educational specialist (ES) serves as a liaison between the medical/rehabilitation and education teams in an effort to optimize the child's transition to school following a TBI. The ES can educate the school staff (and other students if needed) on TBI, assist in development of an individualized education program for the child, monitor the child's progress throughout their schooling, and help adjust educational supports and services as needed.

There are several models for professional training programs for educators of children with TBI that have been implemented and evaluated (Glang et al., 2010). Additionally, thoughtful recommendations have been published to aid the development of a statewide infrastructure for effective educational services for children with TBI (Dettmer, Ettel, Glang, & McAvoy, 2014). In an ideal pediatric TBI program, the services and supports provided by an ES can ease the transition to school and ensure the child's learning environment is appropriate for that specific child. As children are in school 8 hours a day, optimization of a child's educational program and environment can certainly influence the child's ultimate outcome following TBI.

refraining from using infant walkers are strategies for the prevention of falls in infants/toddlers (Schnitzer, 2006). In addition, bicycle helmets are important in the prevention of TBI in children. In fact, biomechanical pediatric skull models have shown that children's bicycle helmets provide a significant reduction in the acceleration and direct compression force, thereby mitigating the risk of more severe TBI (Mattei et al., 2012). Given the high frequency of mTBI in children, methods to prevent concussion in children are essential. Evidence for sport-specific preventive measures to reduce the rate of mTBI in children, such as limited body checking in ice hockey and helmet use when skiing, are emerging, although ongoing research is needed for many potential sport-specific injury prevention strategies (for a comprehensive review, see Emery et al., 2017).

The appropriate use of car seats, boosters, and seat belts has been shown to reduce brain injury in children following a motor vehicle accident (Keenan & Bratton, 2006). The AAP released a policy statement on child passenger safety in 2011 (Durbin & Committee on Injury, Violence, and Poison Prevention, 2011). The statement provides recommendations for best practices, including 1) rear-facing car safety seats for most infants up to 2 years of age, 2) forward-facing car safety seats for

most children through 4 years of age, 3) belt-positioning booster seats for most children through 8 years of age, and 4) lap-and-shoulder seat belts for all children who have outgrown booster seats. Children under the age of 13 years should ride in the rear seats of vehicles. Child safety seats decrease the risk of nonfatal injury by approximately 75% (Zaloshnja, Miller, & Hendrie, 2007) and the risk of fatal injury by 28% (Elliott, Kallan, Durbin, & Winston, 2006). Booster seats decrease the risk of nonfatal injury among 4- to 8-year-old children by 45% compared with seat belts (Arbogast, Jermakian, Kallan, & Durbin, 2009). The AAP also recommends that children should not ride in the flatbeds of pickup trucks and that children or teenagers younger than 16 years should not ride an all-terrain vehicle or a lawn mower.

In school-age children, pedestrian injuries typically occur while the child is crossing the road. Strategies that have been utilized to improve street-crossing skills include group education and individualized behavior training. Individualized training appears to be more successful than group training (Schwebel & McClure, 2010). Programs developed to help teach pedestrian safety included the WalkSafe program. This program has been shown to improve pedestrian safety knowledge of school-age children after

receiving a 3-day educational experience (Hotz et al., 2009). Children ages 5–14 years have the highest rate of bicycle-related injuries. Head injury accounts for 62% of bicycle-related deaths, 33% of bicycle-related ED visits, and 67% of all bicycle-related hospital admissions (CDC, 1995). Bicycle helmets are effective in decreasing head, brain, and facial injuries when used properly. The risk of TBI is reduced by 60% when wearing a bicycle helmet (Attewell, Glase, & McFadden, 2001; Lee, Schofer, & Koppelman, 2005; Thompson, Rivara, & Thompson, 1999). Helmets and protective gear are also recommended for skating, skateboarding, skiing, snowboarding, scooter riding, horseback riding, and motorcycle riding, as well as participation in contact sports such as football, hockey, and lacrosse (Dellinger & Kresnow, 2010; Jagodzinski & DeMuri, 2005; Schnitzer, 2006).

Motor vehicle collisions are the leading cause of injuries in teenagers. Prevention strategies include limiting nighttime driving, limiting driving with teenage passengers, and developing graduated licensing measures (Williams & Ferguson, 2002). As in younger children, the appropriate use of seat belts is imperative and is the law.

To reduce the risk of drowning in children, providing education on the risk of drowning, offering water safety programs, and mandating the use of pool fencing are effective strategies to reduce the incidence of drowning in children. Isolation fencing (enclosing the pool area only) and the use of a dynamic, secure gate with self-latching lock are especially important (Thompson & Rivara, 2000). The AAP Committee on Injury, Violence, and Poison Prevention published a policy statement on effective strategies to prevent drowning in children (2010).

Increased attention to the epidemiology of intentional asphyxiation related brain injury (hanging injuries) has led to efforts to implement more effective national and local suicide-prevention programs. There are also public health efforts to reduce unintentional asphyxiation injuries, such as educational programs to remove pillows and blankets from infant sleep areas and initiatives to discourage cosleeping. In 2016, the AAP published updated recommendations for a safe sleeping environment (Moon & Task Force on Sudden Infant Death Syndrome, 2016).

The CDC has also published a National Action Plan (2012) outlining a childhood injury prevention framework, a comprehensive program using multiple strategies to prevent unintentional childhood injury. Prevention should be addressed at each well-child visit through parent-focused strategies and through education to teachers and community groups as well

as the children themselves. The focus for TBI prevention should be on the appropriate use of seat belts, safe pedestrian behavior, helmet use, prevention of falls, and sports injury prevention. For other etiologies of ABI, the importance of vaccinations, water safety and drowning prevention programs, safe sleeping habits for infants and children, and prompt referral and management for mental health concerns are important preventive measures.

SUMMARY

- ABI encompasses a large group of conditions that result in brain injury with a wide range of severity and outcomes.
- TBI is the most common cause of ABI in children, and AHT is the most common etiology in the youngest children.
- Nontraumatic causes of ABI in children include anoxia/hypoxia-ischemia, stroke, encephalitic/meningitis, and autoimmune disease.
- As ABI occurs during brain development, children are at risk for short- and long-term neurodevelopmental deficits. Persistent functional impairments may involve multiple areas of functioning, including motor, sensory, feeding, communication, cognition, and behavior.
- Restoration and adaptation are the goals of rehabilitation and require a multidisciplinary team including medical professionals, allied health professionals, and education specialists.
- Children should be followed throughout their education to provide academic support and accommodations as needed.
- Most ABIs are preventable. Therefore, brain injury prevention programs are needed, and legislation should be written and enforced to decrease the risk and long-term consequences of ABI.

CHAPTER 24

Developmental Disability in Chronic Disease

Nancy J. Roizen and Catherine Scherer

Upon completion of this chapter, the reader will

- Identify developmental disabilities commonly encountered in children with chronic diseases
- Be aware of the biologic factors that contribute to developmental issues in sickle cell disease
- Know the importance of critical congenital heart disease
- Be aware that children with congenital heart disease associated with a genetic syndrome have lower developmental function
- Note the greater degree of developmental problems in the children with end-stage renal disease compared with mild to moderate chronic kidney disease
- Understand the goal of cancer treatment to maximize chances for survival and minimize the impact on long-term cognitive development

In the United States, the epidemiology of many childhood health conditions has shifted from acute to chronic illnesses, with as many as one in three children living with a chronic health condition (Compas, Jaser, Reeslund, Patel, & Yarboi, 2017). Studies show that various chronic health conditions share deficits in cognition for overall intelligence, verbal and non-verbal intelligence, and aspects of executive function (Compas et al., 2017). The pediatric self-report scales of the Patient-Reported Outcomes Measurement Information System (PROMIS), a program of the National Institute of Health developed to improve patient self-report of chronic disease outcomes, have been used to document outcomes in children with chronic disease,

including those discussed in this chapter. PROMIS studies reveal that children with higher disease severity, as measured by disease-specific measures and recent hospitalizations, report worse outcomes (DeWalt et al., 2015).

This chapter describes five chronic diseases—sickle cell disease (SCD), congenital heart disease (CHD), chronic kidney disease (CKD), lymphocytic leukemia, and brain cancer—that all have documented increased risk of associated developmental disability. The goal of this chapter is to increase appreciation of these risks and to raise vigilance for and improve the management of developmental problems in children with chronic disease.

SICKLE CELL DISEASE

■ ■ ■ CASE STUDY

Kisha is a teenager with sickle cell disease (SCD), which was diagnosed by newborn screening. Throughout childhood, she received prophylactic penicillin, special immunizations, and routine well-child care as well as SCD-specific care. In general, her family has been able to manage the painful sickle crises at home, but once or twice a year she has been hospitalized to control more severe episodes. She began taking hydroxyurea (HU), and for the last 3 years she has not been hospitalized. As a child, she was monitored routinely for stroke risk using transcranial Doppler ultrasonography. She has had normal findings, placing her at low risk for stroke. Kisha will be graduating from high school this year and plans to attend college.

Thought Questions:

What are the ways that the medical problems of the chronic diseases described in this chapter impact the development of children? What are the ways that improvements in medical care have improved the functioning of children with these chronic diseases?

Overview

In the United States, sickle cell disease (SCD) occurs in 1 out of 500 African Americans and 1 out of 1,000 to 1,400 Hispanic Americans (National Institutes of Health: National Library of Medicine, 2018). SCD is an autosomal recessive disorder (see Chapter 1) that results in the production of an abnormal hemoglobin, called hemoglobin S (HbS). HbS is caused by a single point mutation in the beta-globin gene. Red blood cells that contain predominantly HbS become sickle shaped in low-oxygen environments, making them susceptible to **hemolysis** (excessive breakdown of red blood cells). Anemia is the result of this shortened red cell life span. In addition, the sickle-shaped red blood cells can cause blockage of the microvasculature, leading to acute and chronic tissue damage including stroke (Meier & Rampersad, 2017).

Diagnosis and Clinical Manifestations

All states now screen newborns for SCD (Meier & Rampersad, 2017). It is a complex, chronic disorder characterized by hemolysis and intermittent **vascular occlusion** (obstruction). This results in acute complications that can rapidly become life-threatening and chronic complications that can lead to damage to multiple body organs. Acute manifestations include bacterial **sepsis** (blood infection), recurrent vaso-occlusive

pain crises (VOC), splenic sequestration (accumulation of blood cells in the spleen), aplastic crisis (shutting down of the bone marrow), acute chest syndrome (a pneumonia-like condition), and stroke. Long-term medical consequences of SCD include anemia, restrictive lung disease, pulmonary hypertension, **avascular necrosis** (destruction of bone from microvascular occlusion), and delay in physical growth and sexual maturation (Section on Hematology/Oncology & Committee on Genetics, 2002).

Neurological complications of SCD include headaches and strokes. Among affected children, about 10% will sustain overt strokes (Lopez-Vincent, Ortega-Gutierrez, Amlie-Lefond, & Torbey, 2010; Pegelow et al., 2002), and almost one quarter will have silent strokes before their 18th birthday (Pegelow et al., 2002). An **overt stroke** involves a **focal** (localized) neurologic deficit that lasts for more than 24 hours. It results from an occlusion of one of the cerebral circulation vessels (DeBaun & Vichinsky, 2007). In a **silent stroke**, there is evidence of a cerebral **infarction** (tissue death) on a magnetic resonance imaging (MRI) scan, but a focal neurological deficit will be absent on clinical examination (Ohene-Frempong et al., 1998).

Development and Behavior

Studies demonstrate contributions to deficits in developmental functioning from both biologic and social factors. Neurocognitive functioning through the first year of life, as measured by tests of infant development, generally falls within the typical range (Thompson, Gustafson, Bonner, & Ware, 2002). In infants and toddlers, socioeconomic status (SES) correlates with the cognitive subscales (Schatz, Finke, & Roberts, 2004), but SCD severity (as measured by hemoglobin level) does not correlate with Bayley Scales of Infant Development scores (Drazen, Abel, Gabir, Farmer, & King, 2016). One meta-analysis revealed that even children with no evidence of cerebral infarction had small but detectable decrements on IQ measures over time (4 to 5 points overall; Schatz, Finke, Kellett, & Kramer, 2002). Even among school-age children with SCD who had *not* sustained silent or overt strokes, those with greater cerebral gray matter volume (as measured by MRI) had higher IQs than those with less (Chen et al., 2009).

With regard to special academic services, 58% of children with SCD with silent cerebral infarctions were retained or required special education services, compared with 27% without cerebral infarctions and 6% of siblings without SCD (Schatz, Brown, Pascual, Hsu, & DeBaun, 2001). About one quarter to one third of children with SCD have some type of developmental disability, most frequently affecting the cognitive and academic domains (Schatz & McClellan, 2006).

Children with overt stroke have, on average, a 10- to 15-point drop in IQ scores from prestroke levels (Schatz & McClellan, 2006), while silent strokes impart a milder degree of cognitive impairment (Armstrong et al., 2013). Although cognitive patterns are not consistent across all studies, most show that measures of attention and **executive functioning** (cognitive tasks related to taking in, organizing, processing, and acting on information; see Chapter 13) are adversely affected, leading to an attention-deficit/hyperactivity disorder (ADHD) picture (Schatz & McClellan, 2006).

The impact of SCD on families is similar in many ways to the impact of other severe neurodevelopmental disabilities. Factors related to low SES, concerns about the social stigma, and recurrent, unpredictable medical complications contribute to high levels of family stress (Schatz & McClellan, 2006). Children with SCD who are 12–18 years of age are absent from school an average of 12% of the school year, and more than 35% miss at least a month of school (Schwartz, Radcliffe, & Barakat, 2009).

Behavior challenges in youth with SCD are also increased. Both externalizing behavior problems (e.g., aggression, oppositional defiant disorder, and conduct disorder) and internalizing behaviors (e.g., anxiety and depression) are increased, although children with higher baseline IQs have fewer difficulties (Bakri, Ismail, Elsedfy, Ami, & Ibrahim, 2014; Thompson et al., 2003). By contrast, a longitudinal study of social function revealed no significant differences in measures of friendship or social acceptance when compared with peers (Noll, Kiska, Reiter-Purtill, Gerharddt, & Vannatta, 2010).

Treatment

Early identification through newborn screening, the use of hydroxyurea (HU), and caregiver education on the first line of care have provided a major improvement in the care of children with most SCD genotypes. Penicillin prophylaxis prevents bacterial infections

from birth and has dramatically decreased the risk of early death from bacterial sepsis (DeBaun & Vichinsky, 2007; Falletta et al., 1995). With the addition of pneumococcal vaccine, pneumococcal disease has decreased by 70%–90% (Meier & Rampersad, 2017).

HU, a once-daily oral medication, prevents the complications of SCD (see Box 24.1). The 2014 National Heart, Lung, and Blood Institute Evidence Based Management Guidelines for Sickle Cell Disease recommend that all infants 9 months of age and older with SCD be offered HU as a treatment regardless of the frequency or severity of disease (Yawn et al., 2014). Caregiver education has been associated with fewer hospitalizations (Shahine, Badr, Karam, & Abboud, 2015). Family education includes counseling regarding the urgency for prompt evaluation and treatment of febrile illnesses and the acute complications that can cause morbidity and mortality. Although not all children have access, a sickle cell clinic team can provide needed support (see Box 24.2).

Painful vaso-occlusive crises (VOCs) are the most common complaint of older children and adults. Management of VOCs requires a collaborative management plan between the family and the multidisciplinary medical team. Early in the course of managing this problem, comfort measures are used. This is followed by acetaminophen with codeine and short- or long-acting opioids or morphine derivatives. Severe pain episodes require hospitalization and the use of intravenous morphine. The estimated prevalence of opioid addiction in the overall (child and adult) sickle cell population is about 10%, similar to the addiction rate among most chronic pain sufferers in the United States (National Heart, Lung, and Blood Institute, 2017).

Any acute neurological symptoms, including hemiparesis (weakness on one side of the body), akathisia (restless movements), seizures, severe headache, cranial nerve palsy, stupor, or coma, require urgent evaluation for stroke. Strokes are treated acutely with 1) oxygen and blood transfusion therapy, which

BOX 24.1 EVIDENCE-BASED PRACTICE

Hydroxyurea and Sickle Cell Disease

Hydroxyurea (HU) is proving to be a beneficial disease-modifying therapy for sickle cell disease (SCD). HU medication increases HbG and decreases intraerythrocytic (red blood cell) HbS concentration, which decreases sickling and hemolysis. In children, HU therapy has decreased vaso-occlusive crises, acute chest syndrome, and transfusions. Children treated with HU are able to spend less time in pain and in the hospital and are not exposed to the damaging side effects of multiple transfusions. In addition, in a large multicenter study, HU was found to have a strong safety profile, and the participants who were treated with HU had similar growth, development, and organ function as the control group (Meier & Rampersad, 2017).

BOX 24.2 INTERDISCIPLINARY CARE**The Sickle Cell Disease Team**

The sickle cell disease team can vary, but it generally includes professionals in the following disciplines: pediatric hematology, genetics, nutrition, social work, school intervention specialist, and obstetrics/gynecology. The team also works closely with cardiology and neurology.

together decrease the percent of HbS in the blood by dilution, and 2) exchange transfusion, replacing abnormal blood cells with normal blood cells.

For children like Kisha, primary stroke prevention is key to improved outcomes. Regular screening using transcranial Doppler ultrasound (TCD) which assesses blood velocity in the **cervical** (neck) arteries, has been shown to decrease the incidence of overt stroke by 90% (Enninful-Eghan, Moore, Ichord, Smith-Whitley, & Kwiakowski, 2010). When low velocity is found on TCD, prevention of stroke is accomplished by blood transfusion therapy aimed at keeping the HbS concentration low, thereby decreasing sickling. Continuous transfusions, however, can cause an increased iron load, which is treated with chelation therapy. Studies show that treatment with HU is an acceptable alternative (Meier & Rampersad, 2017).

The only currently available cure for SCD is hematopoietic stem cell transplantation (HSCT). Transplants from matched sibling donors have an overall survival rate of more than 90%. Less than 20% of individuals with SCD have a matched sibling donor. As of 2017, individuals with SCD were being recruited for gene therapy and gene-editing trials (Meier & Rampersad, 2017).

Outcomes

With early identification and the use of disease-modifying therapies, the childhood mortality rate for SCD is close to that of the general population; however, life expectancy has not increased in the past 30 years, remaining at half that of the average American (Lanzkron, Carroll, & Haywood, 2013; Meier & Rampersad, 2017; Piel, Steinberg, & Rees, 2017).

Transfusions, HU, and HSCT presently are the mainstays of therapy. Most SCD centers are developing models to make the transition from pediatric to adult care more successful (see Box 24.2). Adolescents and young adults have increased emergency department visits for acute complications, increased readmission rates, and increased mortality around the time of care transition (Meier & Rampersad, 2017). Improvements in the transition process may translate into improved quality of life with increased life expectancy.

CONGENITAL HEART DISEASE**■ ■ ■ CASE STUDY**

Jose is a 5-year-old boy who was diagnosed with tetralogy of Fallot at 8 days of age, when he presented to the emergency department in cardiogenic shock. He had not had any newborn screening with pulse oximetry because the facility where he was born did not routinely perform it. A temporary shunt procedure was performed in the first days of life, and a definitive repair of his heart condition was completed at 4 months of age. His postoperative course was complicated by a prolonged hospital stay of 3 weeks for respiratory issues as he was weaned from the ventilator. He has been followed by his cardiologist who has been monitoring his right ventricular function, and he recently had a cardiac catheterization because of poor exercise tolerance. He will be starting kindergarten with adapted physical education. His mother has been concerned about his ability to focus in preschool.

Overview

Congenital heart disease (CHD) is one of the most common birth defects. CHDs affect nearly 1% of all births per year in the United States (Best & Rankin, 2016). Gilboa et al. (2016) estimated that 1 million children and 1.4 million adults with CHD live in the United States. CHD includes a wide range of cardiac abnormalities of varying severity, with one out of four children born with CHD having a more severe defect, classified as critical CHD (CCHD). The term CCHD is used when the lesion either causes death or requires a surgical intervention in the newborn period. CHDs are the leading cause of death from birth defects in the first year of life (Patel & Burns, 2013).

Several CCHD lesions have been targeted in newborn screening, including the following:

- *Tetralogy of Fallot*, which involves a ventricular septal defect, an overriding aorta, and some degree of pulmonary stenosis that leads to right ventricle hypertrophy.
- *D-transposition of the great arteries (D-TGA)*, in which the aorta is attached to the right side of the heart,

which delivers deoxygenated blood from the body back out to the body, and the pulmonary artery is attached to the left side of the heart, which delivers oxygenated blood from the lungs back to the lungs. (D-TGA is commonly thought of as two circuits of blood running in parallel, rather than the normal flow of blood with the two circuits running in series.)

- *Tricuspid atresia*, in which the tricuspid valve, which connects the right atrium to the right ventricle, does not form. As such, blood cannot flow between those two right heart chambers.
- *Coarctation of the aorta*, which is a severe narrowing of the aorta that makes it more difficult for oxygenated blood from the left side of the heart to circulate out to the body.
- *Total anomalous pulmonary venous return*, in which the pulmonary veins, which return the oxygenated blood from the lungs to the heart, abnormally deliver this blood to the right atrium instead of the left atrium (via abnormal connections or drainage patterns), which leads to mixing of deoxygenated blood returning to the heart with oxygenated blood returning from the lungs.
- *Truncus arteriosus*, which results from abnormal division of the pulmonary and aortic trunks in early fetal development, resulting in a single common outflow tract and valve (called the truncal valve) shared by both the right and left ventricles.
- *Hypoplastic left heart syndrome (HLHS)* (Yabrodi & Mastropietro, 2016), in which the mitral valve and left ventricle are underdeveloped, resulting in severely limited or absent blood flow out of the left heart chambers and leading to the heart essentially having a single ventricle to pump blood to both the lungs and body. HLHS accounts for 4%–8% of cases of CHD (Benson, Martin, & Lo, 2016) but 23% of cardiac deaths.

Cardiac fetal development has a critical window from 2–7 weeks' gestation (Patel & Burns, 2013; see Chapter 6). The etiology of CHD is usually multifactorial, including both maternal risk factors and genetic abnormalities. Maternal risk factors include hyperglycemia associated with type 2 diabetes mellitus (DM) or gestational DM, obesity, maternal medications, tobacco use, illicit drug use, maternal infections, and environmental toxins (during the 3 months prior to conception through the first trimester). Of children with CHD, 35% have a genetic syndrome. Some of the common genetic syndromes (see Chapter 1 and Appendix B) associated with CHD include Down syndrome, **22q11 deletion**

syndrome, **Noonan syndrome**, **Turner syndrome**, **Williams syndrome**, and **VACTERL**. The acronym VACTERL does not refer to an identified genetic cause, but it involves an association of findings that are similar in individuals with the condition, including Vertebral, Anal, and Cardiac defects (40%–80% of patients have CHDs of varying severity), TracheoEsophageal fistula, Renal (kidney) anomalies, and Limb abnormalities. Although about 30% of children with hypoplastic left heart syndrome have identified genetic syndromes, nonsyndromic HLHS is genetically variable in its pattern of inheritance (Benson et al., 2016).

Diagnosis and Clinical Manifestations

The initial diagnosis of CHD is established in the fetus via prenatal fetal echocardiograph and in the newborn period via physical examination, pulse oximetry (a noninvasive measure of oxygen saturation), and postnatal transthoracic echocardiography (see Chapter 6). A study by Oster and colleagues (2014) found that 58% of children with CCHD were identified prenatally versus only 20% of children with noncritical CHD. In 2011, the U.S. Health and Human Services Secretary's Advisory Committee on Heritable Disorders in Newborns and Children endorsed the American Academy of Pediatrics/American Heart Association 2009 recommendation to add pulse oximetry to the uniform newborn screening panel to identify CCHD.

A baby with a positive CCHD screen is then evaluated by a pediatric cardiologist with completion of four-extremity blood pressure measurements and then commonly an echocardiogram to further assess cardiac anatomy (Box 24.3). Despite the CCHD screen, some infants with CHD may still be missed, especially those with coarctation of the aorta (Lannering, Bartos, & Mellander, 2015). Infants may present with tachypnea, a concerning heart murmur, poor perfusion/cardiogenic shock, decreased lower extremity pulses, or a hyperactive precordium (front of chest; Lantin-Hermoso et al., 2017). Some experts recommend genetic testing for children with CHD, especially if there is 1) a positive family history of CHD, 2) comorbid congenital malformations, or 3) other significant comorbidities such as developmental disabilities (Marino et al., 2012; Simmons & Brueckner, 2017; Zaidi & Brueckner, 2017).

Development and Behavior

Neurodevelopmental disability is now determined to be "the most common long-term complication of critical CHD and has the most negative impact on quality of life, academic performance, and opportunity for independence as an adult" (Gaynor, 2014, p. 1790).

BOX 24.3 EVIDENCE-BASED PRACTICE**The Impact of Congenital Heart Disease Screening in Newborns**

- As mentioned in the case study, Jose's critical congenital heart disease (CCHD) most likely would have been found prior to discharge if a pulse oximetry screening had been done after 24 hours of life, thereby preventing a life-threatening presentation to the emergency department.
- As of December 2017, 36 states have laws requiring newborn screening for CCHD and 12 states have regulations on CCHD.
- Sensitivity of screening for CHD with pulse oximetry ranges from 36%–92% depending on the cardiac defect. Specificity is high, with the percentage for false positives around 0.05%.
- States with mandatory CHD screening have had a 33.4% decrease in early infant deaths from critical congenital heart disease and a 21.4% decrease from other cardiac causes over a period of 6 years. States without screening have had no change in the number of infant deaths from CCHD (Abouk, Grosse, Ailes, & Oster, 2017).

Children with CHD have a 30%–50% risk for neurocognitive deficits including ADHD; deficits in executive function, social skills, motor planning, and visual memory; and difficulty with higher-order integration (Calderon, 2016). The etiology of these deficits is multifactorial and includes genetic, prenatal, and postnatal factors such as age at time of surgical correction and severity of illness; additional risk factors include male sex and disadvantaged SES. In addition, altered cerebral blood flow, impaired oxygen delivery to the central nervous system (CNS), and delayed **foldi**ng (central nervous system development; see Chapter 6) have been found in fetal and newborn studies and are thought to contribute to the risk for neurocognitive deficits (Khalil et al., 2016; Laraja et al., 2017; Miller et al., 2007; Rollins et al., 2017). Smaller brain volumes have been seen as early as 25 weeks' gestation (Kahlil et al., 2016). Preoperatively, 20%–40% of children with CCHD have white matter injury (see Chapter 8), and, postoperatively, 50% have evidence of new white matter injury (Miller et al., 2007).

The white matter injury in infants with CCHD preoperatively is similar to the pattern seen in premature infants and has been termed "encephalopathy of CHD" (Volpe, 2014, p. 963). In children undergoing cardiopulmonary bypass, risk factors for neurodevelopmental delays include genetic disorders, lower birth weight, prematurity, longer duration of intensive care, postoperative seizures, and lower SES (Simmons & Brueckner, 2017). Cardiopulmonary bypass (CPB) carries its own set of significant risks to the infant's developing organs, including nonphysiologic temperatures and perfusion rates, hemodilution, systemic inflammation, and myocardial damage (Lee, Blaine Easley, & Brady, 2008; Pouard & Bojan, 2013; Sturmer et al., 2018).

However, it is important to know that despite advances in operative techniques including CPB, neurodevelopmental outcomes have not improved (Gaynor et al., 2015; Marino, 2013).

When compared with peers and siblings without CHD there is an overall 5%–10% decrease in mean IQ in all children with CHD, and the severity of delay correlates to the severity of the CHD. An IQ of less than 70 occurs in 10%–20% of all children with CHD. However, the mean IQs are 90 for nonsyndromic CHD and 70 for syndromic CHD. An IQ of less than 55 is most likely associated with a genetic syndrome or major complication (Figure 24.1; Brosig et al., 2017; Latal, 2016; Naef et al., 2017).

Despite mean IQ scores within the typical range, a high proportion of preschool children with CHD, with or without surgery, are at early cognitive risk. Depending on the severity of the cardiac lesion, early motor delays commonly improve by 3 years of age, but speech, motor, and social-emotional delays can persist. Compared with peers, more children with CHD receive special education (26.9% versus 11.6 %; Riehle-Colarusso et al., 2015). At school age, children with CHD have more learning disabilities, executive function problems (particularly with organization, planning, and self-monitoring), and socio-emotional delays (Gerstle et al., 2016).

Treatment

The potential benefits of fetal cardiac intervention have been known for many years (Box 24.4). Fetal cardiac interventions can alleviate heart dysfunction, prevent them evolving into hypoplastic left heart syndrome, achieve biventricular outcome, and improve fetal

Figure 24.1. IQ range for children with CHD with and without genetic disorders. (Reprinted with permission from Latal, B. [2016]. Neurodevelopmental outcomes of the child with congenital heart disease. *Clinical Perinatology*, 43, 173–185)

survival. Candidates for clinical fetal cardiac interventions are currently restricted to cases of 1) critical aortic valve stenosis with evolving hypoplastic left heart syndrome, 2) pulmonary atresia with an intact ventricular septum and evolving hypoplastic right heart syndrome, and 3) hypoplastic left heart syndrome with an intact or highly restrictive atrial septum as well as fetal heart block. The therapeutic options include prenatal aortic valvuloplasty (repair of the aortic valve), pulmonary valvuloplasty (repair of the pulmonary valve), creation of interatrial communication, and fetal cardiac pacing.

After identification of CCHD in the newborn, medical stabilization may include the use of prostaglandin E_1 (a potent vasodilator) to keep the **ductus arteriosus** (an artery in the fetus that connects the pulmonary artery to the aorta) open until a surgical procedure or cardiac catheterization can be performed. Children with CCHD are often treated with medication to control congestive heart failure to help optimize growth while awaiting their next procedure(s). Each

form of CCHD has a typical type of surgical palliation, but the individual details and timeline for surgery is child specific. For example, infants with D-TGA may require a **balloon atrial septostomy** (a catheter-based procedure) to enlarge the foramen ovale (a fetal connection between the atria; see Figure 6.2 in Chapter 6) until an arterial switch procedure, the currently preferred surgical correction for D-TGA, can be completed (most often within the first 30 days of life). HLHS is commonly treated with a three-stage approach that can include catheter-based and surgical approaches depending on the infant's specific anatomy. These interventions require a team of highly trained professionals (Box 24.5).

Outcomes

With improved surgical techniques, survival rates have increased over the last 20 years, and 80% of children with CHD are living into adulthood. Even children

BOX 24.4 EVIDENCE-BASED PRACTICE

Fetal Cardiac Intervention

Fetal cardiac intervention (FCI) is used in conditions where the fetus is at high risk for prenatal or neonatal death and the intervention may improve survival or alter postnatal disease positively. Pharmacological intervention consists of medication taken orally by the mother or by umbilical vein for fetal arrhythmias. Fetal tachyarrhythmias (a heart rate greater than 160–180 beats per minute) are treated with digoxin and other medications given to the mother. There are also open- and closed-uterus surgical interventions (McElhinney, Tworetzky, & Lock, 2010).

BOX 24.5 INTERDISCIPLINARY CARE**The Congenital Heart Clinic Team**

The congenital heart clinic team includes a pediatric cardiologist, pediatric cardiothoracic surgeon, pediatric interventional cardiologist, and pediatric nurse. Because of the common cognitive and motor delays after cardiac surgery, the team also often includes a pediatric neuropsychologist, speech-language pathologist, occupational therapist, and physical therapist.

with HLHS have a 50%–70% survival rate at 5 years and a 10-year survival rate of 40% (Best & Rankin, 2016). In adulthood, children with CHD may have challenges, including educational underachievement, limited employment opportunities, restricted insurability, and diminished quality of life (Latal, 2016). Quality of life may be affected by medical complications and poor exercise tolerance. However, there are many examples of adults with CHD who live independently, succeed in higher education achievement, become gainfully employed, and have families of their own.

CHRONIC KIDNEY DISEASE**■ ■ ■ CASE STUDY**

At 4 months of age, Juanita's pediatrician identified an abdominal mass and evaluation revealed a rare type of renal cancer, which was present in both kidneys. Six years later, after several surgeries, the cancer has not recurred, but renal function of Juanita's remaining kidney is limited, and it is anticipated that as she grows she will eventually need some type of renal replacement therapy (RRT).

Overview

Chronic kidney disease (CKD) involves a progressive and irreversible loss of renal function that occurs over a period of months to years depending on the disease's underlying cause. CKD is defined in stages based on the severity of renal impairment, with Stage I representing a normal glomerular filtration rate (GFR; a measure of kidney function) and Stage 5 reflecting very poor to no kidney function. End stage renal disease (ESRD) is defined as Stage 5 kidney disease requiring treatment with dialysis or kidney transplantation. The incidence and prevalence of CKD in the U.S. pediatric population is unknown as epidemiological information is limited and imprecise. The 2014 data from the annual report published by the United States Renal Data System (2017) noted the pediatric incidence rate of new cases of ESRD per year to be 14 per 1 million children, or affecting about 10,000 children birth to age 19 years in the United States.

In children, CKD can result from **congenital** (present at birth) causes, acquired diseases, or genetic disorders. In young children, the most common causes of CKD are congenital or inherited disorders, including renal **dysplasia** (abnormal growth), obstructive uropathies (flow of urine blocked; e.g., posterior urethral valves), or reflux nephropathy (urine flowing or refluxing backwards to the kidneys). In older children and adolescents, CKD may occur due to acquired glomerular diseases, including focal segmental glomerulosclerosis (scarring of the glomeruli, which filter the blood) and lupus nephritis, a systemic autoimmune disease that can affect the kidneys (Dharnidharka, Fiorina, & Harmon, 2014).

Diagnosis and Clinical Manifestations

Children may be diagnosed with CKD prenatally via ultrasonography or postnatally through abnormalities in the urinalysis or an elevation in serum **creatinine** (the substance produced by muscle tissue that is filtered from the blood by the kidney). Although the early stages of CKD (Stages 1–3) are usually asymptomatic, children may begin to develop mild symptoms of fatigue or decreased appetite in Stage 4 and develop symptoms of **uremia** (accumulated urinary waste products in the blood) in Stage 5. Uremic symptoms include nausea, **anorexia** (loss of appetite), vomiting, weakness, fatigue, pruritis (itchiness), and deficits in neurocognitive function (Vogt & Avner, 2007).

Many complications occur as CKD progresses, and they often begin to manifest in Stage 3 (when kidney function is 30%–60% of normal). Anemia results from decreased production of erythropoietin by the kidney and is associated with decreased exercise tolerance, weakness, pallor, and fatigue. Cardiovascular complications include hypertension, left ventricular hypertrophy (Mitsnefes et al., 2010), and abnormal lipid metabolism. CKD-related bone disease is usually caused by secondary hyperparathyroidism (excessive secretion of parathyroid hormone in response to a low calcium level) and can result in fractures or changes

of rickets. Growth impairment is multifactorial and results from metabolic acidosis, anorexia, increased caloric requirements due to chronic illness, metabolic bone disease, and abnormalities in growth hormone metabolism (Vogt & Avner, 2007).

Development and Behavior

Children with CKD are at increased risk for alterations and delays in neurocognitive development. In children and youth like Juanita with mild to moderate CKD, neurocognitive functioning overall is within the average range, but 21%–40% score at least 1 standard deviation (SD) below the mean on measures of IQ, academic achievement, attention regulation, or executive functioning (Hooper et al., 2011). In a more recent study from the same group of 124 preschool children with mild to moderate CKD, median scores were in the average range for developmental level/IQ; attention regulation; and parent ratings of executive function, social-behavior, and adaptive behavior. However, 43% were in the at-risk category for two or more of these measures. None of the disease-related variables of GFR, anemia, hypertension, seizures, and abnormal birth history were associated with outcomes (Hooper et al., 2016).

In a study of 90 children and young adults 8–25 years of age with CKD, compared with unaffected controls, those with CKD had poorer performance in attention, memory, and inhibitory control. Lower performance in multiple domains correlated with decreased estimated GFR, a measure of how well kidneys are functioning (Ruebner et al., 2016). In addition, children with CKD and depression have been found to have lower IQ, lower achievement, and lower scores on quality-of-life measures (Kogon et al., 2016).

Children with ESRD are most significantly impacted by their renal disease. Pollack and colleagues (2016) reported on 18 infants who received hemodialysis (HD); eight (44%) demonstrated significant cognitive disability, and four (22%) had seizures. Madden, Ledermann, Guerrero-Blanco, Bruce, and Trompeter (2003) reported on the cognitive development of 16 surviving children from a cohort of 20 who developed ESRD

and required chronic hydroxyurea prior to 1 year of age. The mean IQ was 86, but scores ranged from 50 to 102. In the children with ESRD, the mean IQ improved following transplantation or dialysis, although it was approximately 8 IQ points below the population norm (Moser, Veale, McAlister, & Archer, 2013).

Children with ESRD and their parents report lower health-related quality of life across all domains, including physical health, psychosocial health, emotional functioning, social functioning, and school functioning when compared with their healthy peers (Goldstein et al., 2006). Another study of 402 children with mild to moderate CKD reported similar findings, with parents and children reporting lower health-related quality of life and poor physical, social, emotional, and school functioning as compared with healthy youth (Gerson et al., 2010).

Treatment

Care of the child with CKD includes efforts to slow progression of the disease, correction of metabolic disturbances intrinsic to CKD, provision of nutritional and hormonal support for growth failure, and preparation for renal replacement therapy (RRT) (Noe & Jones, 2007; see Box 24.6). Strategies to protect kidney function include controlling hypertension with salt and antihypertensive medications, reduction of proteinuria, good hydration, and avoidance of nephrotoxic (toxic to the kidney) drugs. Bone disease may be treated with activated vitamin D, and short stature may benefit from recombinant growth hormone injections. Correction of anemia with iron supplementation and recombinant human erythropoietin may result in decreased fatigue and increased exercise tolerance, cardiovascular improvement, and better neurocognitive outcomes (Vogt & Avner, 2007).

When a child reaches ESRD, RRT (renal transplantation, peritoneal dialysis [PD], or hemodialysis [HD]) be initiated. The ultimate goal for the vast majority of children with ESRD is successful kidney transplantation, although if a transplant is not an option, PD (removing waste products through the child's

BOX 24.6 INTERDISCIPLINARY CARE

The Chronic Renal Disease Team

The chronic renal disease team can vary. The team generally includes three types of registered nurses (RNs)—a general nephrology RN, a transplant coordinator RN, and a dialysis RN—as well as a pediatric nephrologist, a social worker, a dietician, and a psychologist.

surface of their abdominal cavity) or HD (removing waste products from the blood as it passes through a machine) may be offered as a bridge to transplantation. The modality chosen is based on family preference and on technical, social, and compliance issues. Of the 9,767 children and adolescents with ESRD in 2015, the most common RRT was kidney transplant (71.2%), followed by HD (17.8%) and PD (9.7%; U.S. Renal Data System, 2017). From 2010–2015, 36% of children received a kidney transplant within their first year of ESRD.

Outcomes

Neurocognitive functioning in children and youth with mild to moderate CKD is within the average range, but 21% to 40% score at least 1 SD below the mean on measures of IQ, academic achievement, attention regulation, or executive functioning (a score of less than 85; Hooper et al., 2011). Children with ESRD are most affected, with IQ being 8 points below average even after RRT.

Patient survival and graft (transplanted kidney) survival after renal transplantation has markedly improved in recent years. The 5-year survival rate of pediatric renal transplant recipients is now 97%, and 5-year graft (transplanted kidney) survival is 74%–84%. Since patient survival exceeds graft survival, the majority of children who receive kidney transplants will return to dialysis and retransplantation (Holmberg & Jalanko, 2016). The most dramatic improvement in graft survival has been in children 5 years of age or younger. In the pediatric age group, adolescents have the worst long-term graft survival, perhaps as a consequence of poor adherence to medication therapy (Dharnidharka et al., 2014). Of the children who receive their first renal transplant, the 16% who have intellectual disability have equivalent short-term graft and patient survival as children with typical intellectual ability (Wightman et al., 2014).

For children with ESRD, during the years 2010–2014, the 1-year adjusted all-cause mortality rate was 27 per 1,000 patient years, which represented a decrease of 31% from the years 2005–2009. Reduced mortality was reported in almost all age categories, with the greatest point estimate of reduced mortality by 42% in children ages 0–4 years. Across all modalities, the most common causes of death were 1) cardiac arrest (cause unknown), 2) withdrawal from dialysis, and 3) sepsis (overwhelming infection) for children ages 0–21 years. The youngest children had similar reported causes when compared with older children and adolescents (U.S. Renal Data System, 2017).

ACUTE LYMPHOCYTIC LEUKEMIA AND BRAIN CANCER

■ ■ ■ CASE STUDY

Sarah has trisomy 21 and was born with congenital heart disease, hypothyroidism, and an elevated white blood cell count, which placed her at increased risk for developing a type of leukemia mainly seen in young children with trisomy 21. She has been monitored by pediatric oncology. Around her third birthday, she developed acute megakaryocytic leukemia. Since receiving chemotherapy, she has been in remission and continues on her original developmental trajectory.

Overview

In 2014, 15,780 children in the United States 0–19 years of age were diagnosed with cancer. The most common cancers in children are acute lymphoblastic leukemia (ALL, a blood cell cancer; 20%) and CNS tumors (18%), with medulloblastomas (cerebellar tumors) being the most frequent brain tumors in children. ALL is associated with multiple chromosomal translocations and intrachromosomal rearrangements as well as specific genetic disorders (e.g., Down syndrome; Hunger & Mullighan, 2015). The etiology of brain tumors is not well defined, but 5% of cases are associated with familial and hereditary syndromes (Kuttesch & Ater, 2007).

Diagnosis and Clinical Manifestations

The clinical presentation of ALL includes bruising or bleeding due to thrombocytopenia, pallor and fatigue from anemia, and infection caused by neutropenia (Hunger & Mullighan, 2015). The diagnosis is usually suggested by an abnormal peripheral blood count showing immature malignant blast cells, which is followed by a bone marrow aspiration to establish the diagnosis (Tubergen, Bleyer, Ritchey, & Friehling, 2016). For CNS tumors, the clinical presentation depends on the tumor location, tumor type, and the child's age. The classical symptoms of a brain tumor include persistent and severe headache and vomiting, but brain tumors can also present with disturbances of equilibrium, gait, and coordination (Kuttesch & Ater, 2007). Evaluating a child suspected of having a brain tumor is an emergency; it includes a history, physical examination, ophthalmological examination, and an MRI scan of the brain (Kuttesch & Ater, 2007).

Development and Behavior

Early studies of survivors of childhood ALL determined that cranial radiation therapy was associated with declines in intelligence (Cousens, Waters, Said, & Stevens, 1988) as well as symptoms of ADHD and impaired school performance, especially in arithmetic computation (Butler & Haser, 2006). Studies of chemotherapy-only treatment for childhood ALL also indicate a specific pattern of neuropsychological late effects. Although verbal subtests have not been significantly different between these two groups, perceptual reasoning skills, working memory, and processing speed have been found to be affected in the chemotherapy-only group (please see Chapter 13 for a discussion of the components of neuropsychological testing). The result is that academic progress in both reading and math is impaired. Children who have experienced relapses have poor neurocognitive outcomes, with 20% displaying IQ scores in the range of intellectual disability (Janzen & Spiegler, 2008).

Studies in children treated for CNS tumors with surgery and cranial irradiation therapy have reported declines in intellectual function and in academic achievement (Butler & Haser, 2006). In a study of 120 children treated with surgery and cranial irradiation therapy for medulloblastoma, 42% had a full-scale IQ score of less than 80 at 5 years following treatment and 75% had a full scale IQ of less than 80 at 10 years following treatment (Hoppe-Hirsch et al., 1990). Deficits were observed in memory, attention/concentration, sequencing, processing speed, visual perceptual ability, and language.

Children with brain tumors who require only surgical treatment can have a range of outcomes. Surgery may result in global intellectual ability remaining intact but with deficits in selected or multiple domains. In addition, more than half of children with brain

tumors who are treated surgically experienced some form of significant psychological adjustment problem, such as depression, externalizing behaviors, and academic problems (Meyer & Kieran, 2002).

Treatment

Improved survival is due to improvements in efficacy of multi-agent chemotherapy regimens and stratification of treatment intensity according to clinical features. It also correlates with the biologic features of the leukemia cells and the early response to treatment. Treatment of ALL begins with induction therapy using systemic and intrathecal chemotherapy. After achieving remission, the next step in treatment involves the administration of intensive combination chemotherapy to consolidate remission and prevent CNS leukemia. This is followed by an 8-week delayed intensification phase using folinic acid to “rescue” normal tissues from the toxic effects of chemotherapy (Hunger & Mullighan, 2015). After remission, most children enter a maintenance phase of chemotherapy that lasts 2–3 years. About 15%–20% of children have a relapse in the bone marrow and less commonly in the CNS or testes, with cure rates much lower after relapse (Tubergen et al., 2016). Bone marrow transplantation may be part of the treatment regimen if there is relapse.

The foundation for treatment of medulloblastomas is the combination of maximal safe **resection** (surgical removal), chemotherapy, and craniospinal irradiation (Bautista et al., 2017; Kuttlesch & Ater, 2007). Several approaches have been taken to decrease irradiation toxicity (Box 24.7). A new approach to decrease irradiation toxicity and increase survival and quality of life, autologous hematopoietic cell transplantation, is being used for initial treatment and recurrent treatment (Box 24.8).

BOX 24.7 EVIDENCE-BASED PRACTICE

Medulloblastoma, Radiation, and Cognition

To decrease neurocognitive deficits in intelligence and academic function related to craniospinal irradiation (CSI) after medulloblastoma surgery, a longitudinal study of risk-adapted (limited) irradiation was conducted. Children with medulloblastoma were divided into average-risk (AR) and high-risk (HR) groups. The children with AR received reduced amounts of CSI. They still had a decline in IQ and less of a decline in academic function, with the most prominent risk factor being younger age. In general, the children in the AR group had less cognitive decline than those in the HR group, suggesting a possible benefit of reduced exposure to CSI, but complex interactions among age, risk, time, and cognitive outcomes were observed, necessitating further study (Mulhern et al., 2005).

BOX 24.8 EVIDENCE-BASED PRACTICE**Autologous Stem Cell Transplantation**

Marrow-ablative chemotherapy for malignant brain tumors followed by tandem autologous hematopoietic cell transplantation has shown promising results. This intervention includes multiple (two or three, depending upon protocol) cycles of high-dose chemotherapy that would otherwise be myelo-ablative (completely wipe out someone's ability to make normal blood cells) but that can be effectively rescued by delivering someone's own (autologous) stem cells to help repopulate the bone marrow after the chemotherapy. In children with newly diagnosed malignant brain tumors, overall survival with no irradiation is greatly improved with this technique (Guerra et al., 2017).

Multidisciplinary approaches to treating sequelae include seizure management, physical therapy, endocrine management with tailored hormone and thyroid replacement, customized educational programs, and vocational intervention, all depending on the individual needs of the child (Kuttlesch & Ater, 2007; see Box 24.9). Initial studies indicate some success using a cognitive remediation program in which the child is guided through exercises that promote sustained, selective, divided, and executive attention control (Butler et al., 2008; Sohlberg, McLaughlin, Pavese, Heidrich, & Posner, 2000). Treatment with stimulant medication (see Chapters 19 and 38) has also improved performance on tests of attention and on parent and teacher reports (Conklin et al., 2010; Netson et al., 2011).

Outcomes

In children in the United States, cancer is the number one cause of death by disease, accounting for 57% of all deaths by disease. Over the last 40 years, the overall survival rate for cancer improved from 10% to 90%. The overall 5-year childhood cancer survival rate is almost 84%, being 90% for ALL and 74% for CNS cancers. In addition, 60% of children have late effects, including secondary cancers, and 12% do not survive these new cancers (Cure Search for Children's Cancer, 2018).

Children who have undergone cancer treatment are more likely than the general population to repeat

a grade in school and to need more learning supports and special education services. Compared with their typically developing peers, children treated for brain tumors are 4 times more likely to repeat a grade, and those receiving cerebral irradiation are 2.5 times as likely to repeat a grade (Barrera, 2005). Compared with siblings, survivors of leukemia and CNS tumors are less likely to finish high school; only those with CNS tumors are also less likely to also complete college (Mitby et al., 2003). Compared with healthy controls, adult survivors of childhood cancers are nearly twice as likely to be unemployed, with those with CNS or brain tumors being nearly five times more likely to be unemployed (De Boer, Verbeek, & Van Dijk, 2006). Minimizing the adverse effects of childhood cancers while maintaining high survival rates with treatment is a goal that has been largely achieved in treatment regimens for ALL but less so in treatment for brain tumors. Improvements in therapy have greatly decreased mortality and morbidity, but advances are needed to achieve optimal neurocognitive outcomes.

SUMMARY

- Children with a spectrum of chronic diseases are more alike than different in the developmental and behavioral challenges that they face.
- Among children with SCD, about 10% will have overt strokes with neurological findings and nearly

BOX 24.9 INTERDISCIPLINARY CARE**The Cancer Team**

The clinic cancer team can vary, but typically includes a pediatric oncologist, a pediatric nurse practitioner, a social worker, and a child life specialist (a health care professional who works with children in and outside of the hospital, helping children deal with illness and disability).

one third will have silent strokes with findings on MRIs.

- Children with CHD have a 30%–50% risk for neurocognitive deficits, including ADHD; deficits in executive function, social skills, motor planning, and visual memory; and difficulty with higher-order integration.
- In children and youth with mild to moderate CKD, neurocognitive functioning overall is within the average range, but 21%–40% score at least 1 SD below the mean on measures of IQ, academic achievement, attention regulation, or executive functioning.
- Cancer survivors of ALL and brain tumors frequently have residual cognitive and academic problems as well as ADHD symptoms.

PART **V**

Associated Disabilities

CHAPTER 25

Visual Impairment

Heather de Beaufort

Upon completion of this chapter, the reader will

- Know the anatomic sources of childhood visual deficit and conditions related to visual impairment
- Gain an understanding of the prevalence and epidemiology of visual deficits, including in children with disabilities
- Understand the basic evaluation of a child with visual impairment, including the ophthalmologic exam and diagnostic studies
- Recognize some of the ways in which a young person with visual disabilities develops differently from a child whose vision is within the typical range
- Be knowledgeable about treatments used to improve or preserve vision, low-vision aids, and vision therapy
- Be aware of outcomes for children with visual deficits

Impaired vision in childhood can have detrimental effects on physical, neurological, cognitive, and emotional development. A severe visual impairment can cause delays in walking, speech, and language development, as well as in behavior and socialization, if early medical and education interventions are not implemented. Visual impairment can occur as an isolated disability or associated with other developmental disabilities. This chapter explores sources of vision loss, sequelae of vision disorders, and the most common ocular pathology. It reviews the basic pediatric eye exam and common tests used in the workup of vision disorders. Treatments for decreased vision and secondary conditions and low-vision aids for the

pediatric population are described. Finally, the effects of blindness on a child's development and outcomes for children with vision impairment are discussed, and relevant educational resources are introduced.

■ ■ ■ CASE STUDY

Mary is a 12-year-old girl, born prematurely at 24 weeks gestational age, who has cerebral palsy and poor vision with associated **nystagmus**. As a result of her **retinopathy of prematurity** (ROP), she has very high nearsightedness. She requires glasses with extremely thick lenses (−18.50 diopters in her right eye and −24.00 diopters in her left eye), which reduces her visual field. Mary benefits

from reading materials with highly contrasted enlarged print on her slant board. Mary wrote the following essay to describe her disabilities and adaptations at school:

One thing I don't like about homework is that sometimes I can't see the print. I have a slant board, which brings my work closer so I won't have to bend over. Because I feel embarrassed, I don't ask to sit closer to the smart board even if I can't see. Also, I need extended time for assignments and tests. I sometimes use a 'talking' dictionary. My handheld magnifier and distance telescope help me, but I don't always use them because my classmates might make fun of me.

At the ophthalmologist's office, Mary's binocular corrected visual acuity measures 20/60. However, with her compound visual disabilities of **optic atrophy**, myopic degeneration, and nystagmus, Mary requires many learning adaptations.

Thought Questions:

What are multiple ways vision can be compromised, making more comprehensive evaluations important? What are the ways that the various vision specialists can help children with vision impairments?

DEFINITIONS, DESCRIPTIONS, AND CLASSIFICATIONS

Causes of Visual Impairment

In order to see well, one must have a healthy eye, optic nerve, and visual cortex (Figure 25.1). A disturbance in any one of these three areas will result in a loss of vision.

Ocular Vision loss may be due to an abnormality of one of the structures of the eye. Light must pass unhindered through the anterior segment of the eye, like the lens of a camera, and strike a functioning **retina**, like the camera's film, in order for clear images to pass to the optic nerve. For example, if the central **cornea**, **lens**, or **vitreous** is cloudy or opacified, such as in a **cataract**, light cannot pass through those structures well and vision is degraded. Furthermore, if the retina is abnormal, as seen in retinal detachment or dystrophy, the retinal ganglion cells do not transmit visual information through the optic nerve properly to the visual cortex.

Optic Nerve Next, the optic nerve transmits visual information from the eye to the brain's visual cortex in order for vision to be processed. In the camera analogy, the optic nerve is the USB cord connecting the

Figure 25.1. The visual pathway. One optic nerve emerges from behind each eye. A portion of the fibers from each crosses at the optic chiasm. An abnormality at various points along the route (upper figure) will lead to different patterns of visual loss (shown as black areas in the lower figures). These are illustrated as A) abnormality at the cortical pathway, B) damage to the optic chiasm, and C) retinal damage.

camera to the computer (or brain) for image processing and storage. Any damage along the length of the optic nerve impairs that transmission of visual information. The optic nerve may never develop properly in utero, as in optic nerve hypoplasia, or it may become damaged due to compression, as in **optic atrophy** or **glaucoma**.

Cerebral/Cortical The final essential component for normal vision is a functioning visual cortex, the section of the brain responsible for visual processing in the occipital lobe. Any pathology in this area, such as stroke or a tumor, will impair vision.

Conditions Related to Impaired Vision and Ocular Pathology

The sections that follow discuss conditions that are related to impaired vision and ocular pathology, including strabismus, nystagmus, abnormal head posture, abnormal color vision, and photophobia.

Strabismus **Strabismus**, or misalignment of the eyes, occurs in about 3%–4% of all children. However, it occurs in 18% of former premature infants and in

55.7% of children with cerebral palsy (Fieß et al., 2017; Dufresne, Dagenais, & Shevell, 2014). There are three main forms of strabismus: **esotropia** (cross-eyed), in which the eyes turn in; **exotropia** (wall-eyed), in which the eyes turn out (Figure 25.2); or a hyperdeviation, which is a vertical misalignment of the eyes (Granet & Khayali, 2011). Strabismus may be apparent all the time or only intermittently, such as when the child tires. Strabismus is one cause of **amblyopia** or decreased vision in children younger than 9 years of age because the brain ignores the input from the deviated eye to prevent **diplopia**, or double vision. Misalignment of the eyes can result from excessive eye focusing, abnormalities in the nerves supplying the eye muscles or the eye muscles themselves, or damage to the brain regions controlling eye movement (Wright, 2007).

Esotropia can be divided into congenital, accommodative, or other causes (such as secondary to poor vision or acquired from a nerve or brain abnormality). Children with congenital esotropia have crossed eyes from birth or shortly thereafter that require early surgical correction. In accommodative esotropia, a child's eyes cross inward due to moderate or high levels of farsightedness. Excess focusing due to this farsightedness causes convergence. Eyeglasses that correct farsightedness decrease the excessive focusing and thus treat this form of esotropia. Neurological problems such as cerebral palsy may alter the brain's signals to the eye muscles and cause strabismus, which may ultimately require surgical correction. This is also true for the child with hydrocephalus, who may develop strabismus as a result of sixth nerve palsy caused by increased intracranial pressure.

Exotropia may be congenital, sensory, or intermittent in nature. Infants with constant exotropia (persisting after 3 months of age) often have contributing neurologic abnormalities and therefore warrant further evaluation. If there is poor vision in an eye, sensory exotropia may develop; this form may

resolve if the vision improves or may require strabismus surgery. Intermittent exotropia is more common in the otherwise-healthy child and is often treated with glasses, patching, convergence exercises, or surgery (Figure 25.2).

Nystagmus By 3–4 months of age a child has developed the ability to fixate on objects. Interruption of this early visual development results in nystagmus, an involuntary back-and-forth (most commonly horizontal) movement of the eyes. Albinism, congenital ocular diseases, and neurologic diseases can all result in nystagmus. Some children have idiopathic infantile nystagmus in which the eyes shake despite normal ocular and neurologic structures. This form is often inherited in an X-linked fashion, and the vision loss secondary to the nystagmus is mild and improves with time. Nystagmus can be latent (only present with occlusion of one eye) or manifest (constant). If the nystagmus is acquired or has atypical features such as rotatory or vertical components, then neurologic evaluation with neuroimaging should be considered, as some brain tumors may present with nystagmus (Papageorgiou, McLean, & Gottlob, 2014).

Abnormal Head Posture Abnormal head postures secondary to an ophthalmologic condition, such as strabismus, **ptosis**, refractive error (especially astigmatism), or nystagmus, is called ocular torticollis. Thus, children with tilted or turned heads should see an ophthalmologist as part of their evaluation. Children with nystagmus turn their head in order to place the eyes where they shake the least and vision is best (the “null point”). In children with strabismus, the eyes may be better aligned in a certain head posture, thus alleviating diplopia. Children with ptosis often lift their chin up to be able to see underneath their lowered upper eyelids.

Abnormal Color Vision Perception of colors can be disturbed for many reasons. Commonly, 1 in 12 males have red-green color deficiency, which is a genetic cause of decreased color perception passed down on the X chromosome. There are also many retinal and optic nerve pathologies that cause decreased color vision, often as an early sign of the disease. Achromatopsia is a serious retinal condition that can cause total loss of color vision.

Photophobia Many congenital and acquired forms of vision loss are associated with sensitivity to light. Severe photophobia can be seen in albinism, aniridia, achromatopsia, and certain corneal

Figure 25.2. The eye muscles (left). Six muscles move the eyeball. A weakness of one of these muscles causes strabismus. In esotropia, the eye turns in, whereas in exotropia, the eye turns out. Esotropia and exotropia of the left eye are illustrated.

dystrophies requiring tinted lenses. It can also be a presenting sign of infantile glaucoma.

Blindness

The definition of blindness from a legal and federal educational perspective is visual acuity of 20/200 or worse in the better eye with correction or a limited visual field that subtends to an angle of not greater than 20 degrees instead of the usual 105 degrees (Individuals with Disabilities Education Improvement Act of 2004, PL 108-446). Individuals with low vision (partially sighted) are defined as having a visual acuity better than 20/200 but worse than 20/70 with correction. Both of these categories are considered visual impairments. People who are legally blind may have considerable useful vision; they may be able to distinguish light and dark, detect objects (20/500 to 20/800), or read enlarged print or regular print using magnification (20/200 to 20/500). Other people who are blind, however, cannot perceive the difference between light and dark. This profound loss of vision even affects circadian rhythms and can disrupt the sleep-wake cycle.

In the educational and rehabilitation fields, blindness is defined functionally as a degree of vision impairment that is so significant that vision cannot be used as the primary channel for learning. A person with low vision can use their vision as a primary channel for learning, but the individual may also need to use other modalities, such as auditory or tactile input, to assist.

PREVALENCE AND EPIDEMIOLOGY

Vision impairment may be due to easily treated causes, such as refractive error and amblyopia, or to more serious structural abnormalities of the eye and brain. Currently, among preschool-age children, 69% of impaired vision is due to uncorrected refractive error and 25% is due to bilateral amblyopia (Varma, Tarczy-Hornoch, & Jiang, 2017).

The leading causes of severe visual impairment in developed countries are cerebral (or cortical) visual impairment (CVI), optic nerve hypoplasia, and inherited retinal disorders. Retinopathy of prematurity (ROP), cataract, glaucoma, and nonaccidental trauma are the most common treatable or avoidable causes of vision loss. Blindness is far more prevalent in developing countries, mostly due to congenital anomalies and corneal opacification secondary to poor nutrition (vitamin A deficiency) and infections such as **trachoma** and onchocerciasis ("river blindness"; Solebo, Teoh, & Rahi, 2017). However, with improvements in nutrition and infectious disease control, there has been a recent shift with

causes of visual impairment more mirroring those in developed countries (World Health Organization, 2007).

VISUAL DEFICIT IN CHILDREN WITH DISABILITIES

Many of the causes of developmental disabilities also influence the visual system, especially prematurity, cerebral palsy, brain injury, Down syndrome, and severe hearing loss. In fact, children with disability have a much higher rate of visual impairment (10.5%) than the general population (0.16%), and more than three quarters of visually impaired children have a significant nonophthalmic disorder (Salt & Sargent, 2014). Processes governing eye movement, alignment, visual acuity, and visual perception may mature slowly, partially, or abnormally in these children. Refractive errors, ocular misalignment, and eye movement disorders are especially common. Because of the links between developmental disabilities and vision problems, it is imperative that a pediatric ophthalmologist conduct an examination as part of the overall assessment for a child with a developmental disability. Treatment of these children must address all the disabilities and use all the senses and abilities that remain intact. A multidisciplinary approach involving a range of educational and health care professionals is essential.

ETIOLOGY AND ASSOCIATIONS WITH SPECIFIC DEVELOPMENTAL DISABILITIES

Refractive Error

Light entering the eye is focused by the cornea and lens. Under optimal conditions, light rays are perfectly refracted onto the retina, resulting in a clearly focused image. If the eye is too long or if the refracting mechanisms of the eye are too strong, the focused image falls in front of the retina, blurring the picture. This is called **myopia**, or nearsightedness. If the eye is too short or the refracting mechanisms are too weak, the image is focused behind the retina, also producing a blurred image. In this instance, the person has **hyperopia**, or farsightedness. The other common refractive problem is **astigmatism**, which typically occurs when the surface of the cornea or lens has an elliptical rather than spherical shape. Because of this, light rays entering the eye do not focus on a single point and the image is blurred (see Figure 25.3). A severe refractive error can impair the development of the visual system, affecting the child's interactions with the world. In children with disabilities, even small refractive errors may be corrected to optimize performance.

Figure 25.3. Refractive errors. If the eyeball is too long, images are focused in front of the retina (myopia). A concave lens deflects the rays, correcting the problem. If the eyeball is too short, the image focuses behind the retina and is again blurred (hyperopia). A convex lens corrects this. In astigmatism, the eyeball is the correct size, but typically the cornea is misshapen. A cylindrical lens is required to compensate.

Amblyopia

Until around age 9, the visual system remains immature and susceptible to a unique type of visual problem called **amblyopia**. Amblyopia is most often unilateral, in which case a structurally “healthy” eye does not see well because it is “turned off” or ignored by the brain. It is prevalent in 1%–3.5% of children and young adults (Gunton, 2013) and can result from deprivation (something obscuring the vision as seen in ptosis or cataract), strabismus, or refractive etiologies such as anisometropia (difference in refractive error between the two eyes) or high refractive error in both eyes.

Cerebral Visual Impairment

CVI is characterized by visual perceptual deficits due to disorders affecting the visual cortex and associated areas. The ophthalmologic examination may be completely normal, though CVI can occur in conjunction with ocular abnormalities as well. Causes include hypoxic ischemic encephalopathy, central nervous system malformations, neoplasia, infection, metabolic neurodegenerative disease, and underlying genetic causes (Solebo et al., 2017). Children with CVI present a variety of classic behaviors, and visual attention can range from mildly impaired to absent. Early on, parents note that their infant responds to light and dark but may not look directly at the parents’ faces, even at

6 months of age. Later, when the child is more alert, the parents observe intermittent or brief visual tracking behavior. The child may “look over” items but not directly at them. Also, these children can see better peripherally if the object or they are moving. Visual function is often noted to improve with time in CVI, and visual stimulation therapies may improve visual function in some patients (Matsuba & Jan, 2006).

Optic Nerve Hypoplasia

In optic nerve hypoplasia (Figure 25.4), a smaller than normal optic nerve with impaired connection to the brain results in decreased vision uncorrectable with glasses. Midline structures in the brain can also be underdeveloped, including the pituitary gland. Children with unilateral or bilateral optic nerve hypoplasia should undergo neuroimaging, especially when there is poor growth, to rule out any abnormality in the pituitary gland that could result in a growth hormone deficiency or other hormonal imbalance. One of the most common causes of visual disability, optic nerve hypoplasia, is often associated with other developmental disabilities.

Optic Nerve Atrophy

Atrophy of the optic nerve (Figure 25.4) is any damage that occurs along the length of the nerve that results in

Figure 25.4. Photographs of optic nerve hypoplasia (congenitally small nerve) and optic nerve atrophy (pale, damaged nerve). (Photos courtesy of Carmelina Trimboli.)

decreased central, peripheral, or color vision. There are many causes of optic atrophy, including compression due to a tumor, hydrocephalus or trauma, ischemia, infection, hereditary causes, neurodegenerative etiologies, toxins, and nutritional deficiencies.

Retinopathy of Prematurity

In infants, the most common cause of retinal damage is ROP, as in the case of Mary (see Figure 25.5). The incidence of this condition is increasing as more premature infants worldwide survive due to advances in neonatology care. When an infant is born very early (gestational

age 30 weeks or less) or born weighing less than 1,500 grams, it is at increased risk for developing ROP. Excess oxygen exposure to the still developing retinal vasculature, among other factors, can result in abnormal vessel growth and traction retinal detachment. Treatment of severe forms of ROP includes peripheral retinal laser; retinal detachment repair surgery; and, more recently, intraocular injection of antivascular endothelial growth factor, known as Avastin. The neonatology practice of limiting excessive oxygen supplementation can also reduce the risk of ROP (Sternberg & Durrani, 2018).

Despite treatment, children with ROP may have significant visual impairments. Nearly 50% of children

Figure 25.5. Retinopathy of prematurity. Blood vessels in the retina proliferate (left). Eventually they stop growing, leaving a fibrous scar that contracts in the most severe cases and pulls the retina away from the back of the eye, causing blindness (right). (From Batshaw, M. L., & Schaffer, D. B. [1991]. *Vision and its disorders*. In M.L. Batshaw, *Your child has a disability: A complete source book of daily and medical care* [p. 165]. Baltimore, MD: Paul H. Brookes Publishing Co., Inc. reprinted by permission. Copyright © 1991 by M.L. Batshaw; illustration copyright © 1991 by Lynn Reynolds. All rights reserved.)

born at 27 weeks' gestational age or less have been found to have subnormal visual acuity and/or strabismus (Haugen, Nepstad, Standal, Elgen, & Markestad, 2010). In addition, extremely low birth weight infants (those weighing less than 1,000 grams) are at increased risk of sustaining neurologic insults, such as intracerebral hemorrhage and periventricular leukomalacia, that further impact vision by causing CVI and optic atrophy. Infants born at younger gestational ages also more commonly have neurodevelopmental disabilities (Leversen et al., 2011), which can be compounded by the effects of ROP on vision.

Cataract

Cataract is a defect in lens clarity (see Figure 25.6). Although cataracts primarily develop during adulthood, they also occur in 0.01%–0.15% of children, accounting for about 8% of blindness in children living in developed countries (Liu, 2017). In developed countries, the majority of cataracts do not have a known etiology. However, in developing countries, preventable infections, such as prenatal rubella, account for a large proportion of childhood cataracts (Vinluan, Olveda, Olveda, Chy, & Ross, 2015). A cataract appears as an opacity in the pupil of one or both eyes. If severe and left untreated in childhood, it will cause deprivation amblyopia. All newborns are screened by their pediatrician, and any child with a suspected cataract should see a pediatric ophthalmologist promptly. A cataract may be an isolated abnormality or part of a syndrome or disease, in which case a referral for a genetics evaluation may be warranted. For example, children with certain inborn errors of metabolism (e.g., galactosemia), congenital infections (e.g., rubella), or eye trauma or who are taking certain medications may develop cataracts.

Figure 25.6. Photograph of a cataract; the lens opacity is seen through the pupil.

DIAGNOSIS AND CLINICAL MANIFESTATIONS

Pediatric Ophthalmology Exam

The pediatric eye exam begins in the waiting room. As the child is called to be examined, their visual function and head posture are assessed as they move into the room. Once in the room, a history is obtained from the caregivers and, if possible, the patient. Medical providers must pay close attention to the family ocular history, comorbidities, medications, visual functioning at home and school, and ocular concerns such as photophobia and ocular pain. Generally, depth perception is tested first, either via stereotesting with 3-D glasses or Worth 4 dot testing with red/green glasses. Next, a motility exam is performed at distance and near fixation to determine if strabismus is present. Visual acuity and color vision testing appropriate to the child's age and functioning level are then performed. In infants or nonverbal children, this may involve evaluating a response to light, the ability to fix on and follow an object, an optokinetic reflex with an optokinetic nystagmus spinning drum, and/or preferential looking. An external exam looking at the eyelids and surrounding structures is then performed. Pupils are evaluated with a swinging light test in light and dark conditions. An exam of the anterior segment, or front of the eye, is performed with either a penlight or, in more cooperative patients, a slit lamp to evaluate the cornea, conjunctiva, anterior chamber, iris, and lens. At this point, cycloplegic dilating drops are generally placed in each eye, and the patient must wait 40 minutes while the pupils dilate and accommodation relaxes. The child is then reexamined by the ophthalmologist with a **retinoscope** (a magnifying, streak light source) to determine, using lenses of varying powers, the refractive error. Eyeglasses can then be prescribed as needed. The final portion of the exam is a dilated fundus exam to evaluate the vitreous, retina, and optic nerve in each eye.

Diagnostic Studies

Beyond the pediatric ophthalmology exam, further diagnostic studies include visual field testing, optical coherence tomography (OCT), and visual electrophysiology

Visual Field Testing The visual field test is a method of measuring an individual's scope of vision. Visual field testing maps the peripheral visual fields of each eye individually. Because it is a subjective examination, requiring the patient to understand the

testing instructions, it is very difficult to perform for young children or individuals with significant cognitive impairment. This testing is important, however, because visual field deficits can functionally interfere with learning and daily living even when visual acuity is normal.

Optical Coherence Tomography OCT is a more recent form of noninvasive imaging that uses the reflection of light to create high-resolution pictures and measurements of different parts of the eye, including the cornea, iris, retina, and optic nerve, to aid in diagnosis and monitor treatment of certain eye conditions (see Figure 25.7). It has become an invaluable tool for monitoring optic atrophy, as the thickness of the retinal nerve fiber layer, which is decreased in this condition, can be quantitatively measured and monitored over time.

Visual Electrophysiology Electrophysiological testing includes electroretinograms (ERGs) and visual evoked potentials (VEPs) to determine whether the vision problem lies primarily in the eyes or the brain (Almoqbel et al., 2008).

Electroretinogram An ophthalmologist may decide to obtain an ERG when the retina looks normal but vision is absent or very poor, as is sometimes seen in infants with nystagmus. The ERG tests retinal functioning by evaluating the quality of the response of retinal cells (rods and cones) to light stimuli. In ERG testing, modified contact lenses are placed on the corneas of the child after putting in topical anesthetic

drops. Depending on the type of equipment used, one to three electrodes are also affixed to the face and/or body. Lights are momentarily flashed in the child's eyes under different conditions while a computer analyzes the information received from the electrodes and from leads attached to the contact lenses. This test may also be performed under anesthesia for children who would not tolerate wearing a contact lens while awake.

Visual Evoked Potential VEP testing is a form of EEG that focuses on the occipital lobe in order to determine if central visual function, from the macula to the occipital lobe, is intact. It is often used in the evaluation of possible CVI. It may also be considered in a patient with poor vision once an ERG indicates that the retina is functioning normally.

Impact on Communication, Psychosocial Skills, and Academics

One might expect severe visual impairment to result in lags in early childhood development. Studies that have examined these issues have indeed found developmental delays, but the delays appear to be dependent on the amount of residual vision and the presence or absence of associated developmental disabilities. The early development of children with vision better than 20/500 and with no other severe associated impairments may approximate that of sighted children. In addition, children with early developmental lags related to more severe visual impairments can catch up with their peers and function in the typical range by school age provided that there are no associated severe disabilities (e.g., cerebral palsy, intellectual disability,

Figure 25.7. OCT image of the central part of the retina called the macula. On the left, the picture shows a slice through the retina with each layer visible. On the right is a color-coded retinal thickness map.

or hearing impairment). Approximately 30% of children with profound visual impairment are at risk of static or regressed cognitive development in the second year of life (Salt & Sargent, 2014). The origin of the visual loss (eye, optic nerve, or brain) does not seem to influence the degree of delay in milestone acquisition. Additionally, most tests of infant development are based primarily on performance of visual skills and may not be optimal in evaluating infants with severe visual impairment as they overestimate delay. Alternative developmental scales that are not visually based should therefore be used to help in evaluation and educational planning (Arzubi & Mambrino, 2010).

Motor Development Initially, an infant who is blind has similar motor activity to sighted infants, but by 2 months of age, they are noted to keep their head bent lower and have abnormal fidgety movements and ataxia. They keep their hands fisted and held at shoulder height until at least 5 months of age, later than sighted peers. Later in infancy, prewalking motor skills such as crawling and standing are also delayed, although the ability to sit occurs at a normal age. Walking, in the absence of other disabilities, is often delayed to 18 to 24 months of age. Visual impairment also affects fine motor skills and balance (Figure 25.8). Given that mobility is the main way that young children explore their environment, an associated motor delay can have an impact on cognitive and social development as well (Cuturi, Aggius-Vella, Campus, Parmiggiani, & Gori, 2016). Decreased motor development in visually impaired

children correlates with being less physically fit. There is a higher rate of obesity than in sighted children age 6–12 years, and so promoting a healthy and active lifestyle in children with visual impairment is especially important (Houwen, Hartman, & Visscher, 2010).

Language Development Though infants who are blind may imitate sounds earlier than sighted infants, they may show delays in combining words to express their needs. However, in the child who is blind with average intelligence, speech and language reach typical levels by school age, although speech is accompanied by less body and facial “language” and conversation skills may be less developed. They may ask less questions and use adjectives less. Differences also surface in the use of words and difficulty with pragmatics and pronouns (e.g., saying “you” for “I”; Perez-Pereira & Conti-Ramsden, 1999). See Box 25.1 for more on the tie between language development and vision.

Psychosocial Development Being unable to establish eye contact with parents could have an impact on the infant’s attachment and socialization skills. Preverbal communication, which is dependent on visual observation and imitation, could be delayed. It is interesting to note that the child with congenital blindness may be unaware of having an impairment until 4–5 years of age. In the school-age child, however, social skills impairments may be related to social isolation and poor self-image. Therefore, including a child in a program with

Figure 25.8. Age of attainment of motor skills in sighted and blind children. The motor development of a blind child is delayed. BOX 25.1 EVIDENCE-BASED PRACTICE**Reading Disabilities and Vision**

Dyslexia is a language-based reading disability present in approximately 20% of children that is often mis-categorized as a vision problem. Though vision impairment may coexist with dyslexia, there is not a higher rate of vision problems among dyslexic children than the general population (Handler & Fierson, 2017). If vision is thought to be a contributing factor to reading difficulty by a child, their parents, or their educators, they should be referred to an ophthalmologist for evaluation and treatment. Dyslexic children should be treated by an educational therapist specializing in the application of phonics. Dyslexia treatments involving behavioral vision therapy, eye muscle exercises, or colored filters or lenses have not been scientifically proven to be efficacious (American Academy of Pediatrics, 2009).

typically developing children should include an agenda to promote socialization (Cochrane, Marella, Keefe, & Lamoureux, 2011). Vision impairment is also correlated with high rates of mental health issues, especially anxiety, and the diagnosis of psychopathology and subsequent treatment may differ from patients with normal vision (Saisky, Hasid, Ebert, & Kosov, 2014).

MONITORING, SCREENING, AND EVALUATION

As vision impairment (e.g., amblyopia) is the most common potentially treatable disability of childhood, robust screening is necessary to correctly identify affected children and to ensure they are referred for treatment at a young age when vision can still be rehabilitated. With early childhood screening, the risk of persistent amblyopia at 7 years of age is cut in half. Unfortunately, currently less than one in five children receive adequate vision screening. Primary care providers should follow the American Academy of Pediatrics Policy Statement on eye examination guidelines (American Academy of Pediatrics, American Academy of Ophthalmology, American Association for Pediatric Ophthalmology and Strabismus, & American Association of Certified Orthoptists, 2015). Chapter 7 details these age-specific screening guidelines, which include evaluation for the normal and symmetric red reflex from both eyes spontaneously (the red reflex test), the

corneal light reflex or cover test of ocular alignment, and developmentally appropriate visual acuity testing. Any child failing a visual screen should be directed to the care of a pediatric ophthalmologist.

Assessing the visual function of children with developmental disabilities is critical in determining the best interventions. It is important to spend time asking the caregivers from their perspective what the child can see or not see, as they observe the child in multiple lighting conditions and in different settings, as well as when the child is rested or tired. Of importance is that their assessment, while not scientific, is more than a one-time snapshot of visual ability. The caregiver's perspective combined with the clinical examination can better capture what the child actually sees, doesn't see, and what accommodations assist him or her to see better. Students who are blind or low vision undergo a formal "functional visual assessment" by a teacher of the visually impaired. This multidisciplinary perspective can be invaluable.

TREATMENT, MANAGEMENT, AND INTERVENTIONS**Refractive Error Correction**

Glasses are the most common way refractive error is treated in childhood. If indicated, an ophthalmologist or optometrist (see Boxes 25.2 and 25.3) may prescribe glasses to their pediatric patient to improve vision, treat

BOX 25.2 INTERDISCIPLINARY CARE**Role of the Optometrist**

Optometrists are health care professionals who are licensed to evaluate and treat vision changes by prescribing glasses or contact lenses. In some states, they may also treat medical eye conditions by prescribing eye drops. Some subspecialize to become developmental optometrists or low-vision specialists.

BOX 25.3 INTERDISCIPLINARY CARE**Role of Pediatric Ophthalmologist**

Pediatric ophthalmologists are physicians who evaluate and treat children with visual or ocular complaints. They may prescribe glasses; treat amblyopia with patching or atropine drops; treat infections or inflammation with eye drops or systemic medications; and perform ocular and orbital surgeries, including strabismus surgery, cataract surgery, and glaucoma surgery. They also treat adults with strabismus despite being pediatric specialists.

amblyopia, or even correct eye crossing, as in accommodative esotropia. Getting a child to wear glasses at all can sometimes be a challenge, but most children adapt well after the first 2 weeks of wear. In certain cases, especially in far-sighted patients, an atropine eye drop may be prescribed in order to facilitate glasses acceptance. A properly fitting frame with a strap or comfort cables around the ears can help. For children with Down syndrome, Specs4us frames have been specifically developed to better fit their facial structure. For patients with severe photophobia, tinting the lenses can significantly improve visual function and comfort.

Contact lenses are less commonly used in childhood due to the difficulty inserting the lens in this population. However, there are certain high refractive error conditions that are best treated with contact lenses because the glasses would be simply too heavy for a child to wear. In aphakic children who have undergone cataract extraction at a young age and lack a lens, they often are prescribed “aphakic” contact lenses of high powers. Contact lenses may also be useful in patients with **aniridia**, or a congenital lack of a normal iris structure resulting in disabling photophobia. These tinted lenses help block excessive amounts of light from entering the eye, making the child with aniridia more comfortable.

There are many children who, due to a medical condition such as autism, do not tolerate wearing

glasses at all. There is ongoing research to determine if laser refractive surgery, which is typically reserved for adult patients, is a safe and efficacious way to treat amblyogenic refractive error in this population (Stahl, 2017).

Amblyopia Treatment

Depending on the cause and degree of amblyopia, treatment may involve glasses, patching, or atropine penalization to blur the vision of the better-seeing eye, encouraging the brain to use and develop the vision of the amblyopic eye (Gunton, 2013). Ophthalmic surgery may be needed in cases of deprivational or strabismus amblyopia. If left untreated, amblyopia can lead to lifelong visual impairment. See Box 25.4 to learn more about recent research on amblyopia treatment.

Ophthalmic Surgeries

Surgery is sometimes necessary in order to improve vision or prevent further loss of vision. Cataract surgery may sometimes be performed as young as 1 month of age in order for vision to develop properly. When an eye is deviated and being ignored by the brain, as in strabismic amblyopia, strabismus surgery can help align the eye so that the brain starts using the

BOX 25.4 EVIDENCE-BASED PRACTICE**Amblyopia Treatment**

Large-scale, multicentered, randomized trials by the Pediatric Eye Disease and Investigator Group have addressed many questions about amblyopia treatment. Results have shown that amblyopia treatment in general is highly successful, with resolution of amblyopia in approximately 75% of children (younger than 7 years old) when treated with patching or atropine, which were found to be equally equivalent treatment modalities. When either patching or atropine penalization fails to improve vision further, switching to the other treatment modality should be attempted. Surprisingly, almost half of older children (13–17 years of age) with previously untreated amblyopia had improvement (10 or more letters) with treatment despite being several years past the classically defined period of visual development (Gunton, 2013).

eye again. Strabismus surgery may also be performed to straighten a child's head posture in cases of ocular torticollis. Glaucoma surgery is necessary when the eye pressure is elevated to prevent damage to the optic nerve and subsequent blindness if left untreated. When the eyelid is droopy and covering the pupil ("ptosis"), vision can only develop properly when the eyelid is surgically elevated. This surgery may be done in infancy, like cataract surgery, so that the vision can develop prior to permanent poor vision and nystagmus setting in after 3 months of age.

Genetic Advances

Clinical trials are currently evaluating targeted gene-replacement therapy for genetic forms of visual impairment in which a normal copy of a patient's defective gene is introduced under the retina by a viral carrier. Clinical studies replacing the *RPE65* gene in patients with retinitis pigmentosa have shown improved visual function, and this is now an available therapy for patients over 12 months of age (Russell et al., 2017). Other forms of inherited blindness, such as Leber's hereditary optic neuropathy, are being studied for possible gene therapy treatments as well.

Low-Vision Aids

If vision remains poor after vision has been optimized through the use of glasses, amblyopia treatment, or indicated surgeries, low-vision aids become essential tools for a child to function well at school and home. Low-vision aids can be divided into three categories; optical, nonoptical, and electronic. For severe vision loss, braille and certain orientation and mobility techniques are essential for education and daily living. (See Box 25.5 to learn about low-vision specialists.)

Optical Optical aids can be divided based on their use for near- or distance-vision activities. For

near-vision activities like reading, magnifiers can be single vision spectacle (glasses), handheld, stand, or dome type. Depending on a child's other disabilities, certain magnifiers may work better than others; for instance, if a child has poor motor control, a handheld magnifier may be difficult to use, although a stand or dome magnifier might work well. For distance vision, one may use an extra-short-focus monocular telescope, and these may be either handheld or spectacle mounted. (See Figure 25.9 for examples of low-vision aids.)

Nonoptical Depending on how reduced a patient's vision is, the font size of their work may need to be enlarged. The American Foundation for the Blind recommends using an 18-point or higher font size, non-decorative font styles such as Arial, and bold print, as well as avoiding all caps and italicized letters. Spacing should be at least 1.5 spaces between each line, and reading material on glossy paper should be avoided.

A reading stand or slant board can be very useful for low-vision patients to bring their work closer to their eyes so that they do not have to lean over a flat table. Moreover, a person with low vision may need three times as much light as a person with typical sight. A gooseneck lamp can be useful to bring the light close to the material being viewed. It should be positioned on the same side as the viewing eye if a patient is monocular, and it should not be shining toward the patient's eyes, as that may cause glare.

Glare in some low-vision patients can significantly decrease their visual function. Glasses and contact lenses can be made with varying degrees of tint to improve this. Simple measures like side shields on glasses, wearing a hat, and lighting placement can also reduce glare. Lastly, a typoscope is a piece of durable black plastic with a central cut out section placed over reading material to aid in reading by eliminating glare from the surrounding white page, allowing the user to focus on the desired text. It can be especially useful in patients with hemianopia who have lost half of their visual field.

BOX 25.5 INTERDISCIPLINARY CARE

Role of the Low-Vision Specialist

Low-vision specialists are optometrists or ophthalmologists who work with low-vision patients to evaluate their vision impairment and recommend appropriate optical and nonoptical low-vision aids. They also train their patients how to use each different aid. They may work closely with rehabilitation teachers, orientation/mobility specialists, and occupational therapists to help their patients function visually to the best of their ability.

Figure 25.9. Low-vision aids include the following: A) single-vision spectacle magnifier glasses, B) handheld magnifiers, C) handheld magnifier with LED light, D) stand magnifier, E) dome magnifier, F) handheld monocular telescope, G) video magnifier.

Electronic Individuals with severe visual impairment greatly benefit from the omnipresence of computers in today's society. Voice-recognition software permits individuals to input instructions and dictate to computer applications. In addition, there are various devices that "talk," including calculators, clocks, computers, and other assistive technology devices that provide auditory information. Closed-circuit televisions, electronic readers, and high-contrast monitors can be very useful in the education and daily living of the school-age child with low vision. Large-print computer programs, such as ZoomText, enlarge and

enhance images and writing on a computer or tablet screen. Screen readers are software programs that convert digital text into speech or braille output (Benedict & Baumgardner, 2009).

Communities are also becoming more accessible to individuals with visual impairment by implementing elevators that announce floors, crosswalk indicators that beep when it is safe to cross the street, and ramps. The use of personal global positioning system (GPS) software is also beneficial, as it supplements use of a mobility cane. A new technology called Aira uses video-equipped smart glasses, artificial intelligence,

and live, remote human assistance to help low-vision patients navigate their environment and is being offered in some grocery stores and on college campuses.

Braille Although some children will succeed best with optical aids and devices and large-print books or electronic readers, others, especially those with severe vision loss (20/400 or worse), may succeed best with braille or a combination of learning media referred to as dual media. Braille is a code formed from a series of raised dots on a page that are read from left to right, as print is read visually (Massof, 2009). Readiness for braille begins in kindergarten (Roth & Fee, 2011). Fine motor skills and tactile sensitivity skills are developed first as these are essential in the learning process. When the child is able to recognize small shapes, differentiate between rough and smooth, and follow a line of small figures across a page, the learning of the braille alphabet can begin.

Children with severe visual impairments should also learn to type on a computer. Braille keyboards exist in two forms: a pure braille keyboard and a conventional QWERTY keyboard with braille keys. Digital text can be converted to braille on a refreshable braille display. In addition, a wide variety of books on tape are available from Recording for the Blind & Dyslexic (see <http://www.rfbd.org>) and from bookstores and libraries. It is critical that a visually impaired child has all of the equipment necessary for learning and independence and that is appropriate for their particular needs. With these tools, children with severe visual impairments are better equipped to succeed in the general education environment.

Orientation and Mobility Techniques As soon as an infant is diagnosed with a severe visual impairment, he or she should be entered into an early intervention program, including working with an orientation and mobility specialist. The focus should be to increase skills in other senses, to improve body concept and awareness, and to promote locomotion and active exploration of the environment (Roman-Lantzy, 2007).

While awake, infants should be placed on their stomach rather than on their back to strengthen neck and trunk muscles. The young child with a severe visual impairment must explore the world through touch and sound. Brain imaging studies have shown that in people who are blind from an early age, the visual cortex can be used for processing tactile and auditory information (Theoret, Merabet, & Pascual-Leone, 2004). Therefore, parents and therapists should place or store textured and sound-producing toys at a height the child can reach. If there is any usable vision,

the child should be encouraged to take advantage of it; bright colors should be used, and the child's vision and attention should be directed verbally toward them (Holbrook, McCarthy, & Kamei-Hannan, 2017). It is very important for the parents, teachers, and therapists to verbally cue the child with information prior to being touched/handled in order to eliminate any resistance to touch (tactile defensiveness; Downing & Chen, 2003). The child's name should be used frequently to encourage inclusion in conversations and to ensure that the child will respond to questions in the absence of verbal cues. There also should be a verbal explanation before, during, and after a task is performed (Ferrell, 1984). While the child is moving from one space to another, the purpose of the move and the orientation of the space should be explained.

Orientation encompasses such skills as laterality and directionality. For visually impaired children, there are three main devices used for orientation and mobility training: precanes, powered mobility devices, and virtual reality technology. Precanes can include simple doll strollers or kiddie canes to help a child who is blind navigate their environment, getting auditory and tactile feedback as they move around. Powered mobility devices, frequently used in cerebral palsy, can have utility for children as early as 3 years of age. Virtual reality technology ("BLINDAID") has been developed to train the vision impaired, using auditory, thermal and sensory feedback to improve mobility in a safe but realistic environment. For older children, Ultrabike, which uses ultrasound technology to help the visually impaired cyclist navigate, has been developed (Cuturi et al., 2016).

Vision Therapy

There are many different types of vision therapy available today. Orthoptic vision therapy involves eye exercises to treat eye movement abnormalities, especially convergence insufficiency. A common exercise is a pencil pushup, where a patient focuses on an object as it is brought repeatedly toward their nose in order to improve their ability to converge, or turn, their eyes inward. Behavioral/perceptual vision therapy is performed by developmental optometrists to improve visual perception and processing; however, thus far, this has not been scientifically proven to be effective treatment. Vision therapy for correction of myopia is another recent field within optometry that uses special contact lenses, bifocal glasses, and dilute atropine drops to slow progression of near-sightedness. Its long-term utility is yet unknown. (See Box 25.6 to learn more about the role of the vision therapist.)

BOX 25.6 INTERDISCIPLINARY CARE**Role of the Vision Therapist**

Vision therapy is a subset of optometry that can be described as physical therapy for the visual system. It involves an optometrist-led program of certain visual activities to treat certain visual problems. It may include the use of prisms, lenses (“training glasses”), filters, computer programs, balance boards, and metronomes, among other things. There is controversy regarding this field as behavioral vision therapy has been scientifically unproven.

OUTCOMES

Outcomes for the child with severe visual impairment depends on the amount of residual vision, the presence of associated disabilities, the motivation of the child and family, and the skills of the child’s teachers and therapists. With severe visual impairment, there may be effects on overall health, self-perception, educational attainment, occupational choices, and other social factors (Davidson & Quinn, 2011). In general, less severe visual impairment and the absence of associated disabilities predict typical development and good outcomes for independence and occupational success. Early intervention and adequate support can help a visually impaired child lead an independent and successful life.

SUMMARY

- Vision impairment arises from a defect in ocular structures, the optic nerve, the visual cortex, or a combination of these areas.
- Vision disorders may result in strabismus (esotropia, exotropia, or vertical eye misalignment), nystagmus, an abnormal head posture, abnormal color vision, or photophobia.
- The most common causes of severe visual impairment include CVI, optic nerve hypoplasia, and inherited retinal disorders.
- Children with developmental disabilities are more likely to have visual impairment.
- Severe visual impairment can have an effect on motor, language, and psychosocial development.
- Vision may be improved with refractive error correction, amblyopia treatment, ophthalmic surgery, or gene replacement therapy.
- Low-vision aids include optical and nonoptical aids, electronic devices, braille, and orientation and mobility techniques.

CHAPTER 26

Deaf/Hard of Hearing Plus

Susan E. Wiley

Upon completion of this chapter, the reader will

- Recognize that risk factors that contribute to a higher likelihood of hearing loss are more prevalent in children with disabilities than in the general population
- Understand adaptations for testing that are helpful in children who are Deaf/hard of hearing and who are suspected as having a developmental disability
- Identify resources for children who are Deaf/hard of hearing Plus (those with developmental or medical complexities)

Children who are Deaf/hard of hearing (D/HH) are at higher risk than the general population to have developmental disabilities (Boyle et al., 2011; Gallaudet Research Institute, 2011). It is understandable that clinicians and parents may attribute a child's delays to the presence of hearing loss. However, this view can contribute to delays in the identification of developmental needs and can lengthen the time it takes to access broader supports, strategies, and expertise beyond those focusing on deafness. When children experience delays in accessing effective supports, they lose some of the recognized benefits of early intervention (Kennedy et al., 2006). In this chapter, the reader will learn more about factors that place children who are D/HH at greater risk for developmental disabilities, and approaches to the recognition and identification of developmental needs will be discussed. While resources for children who are D/HH with a developmental disability are limited, the chapter will provide guidance on resources for various developmental needs and family support.

■ ■ ■ CASE STUDY

Abigail is a 9-year-old girl with partial trisomy 9 and intellectual disability. Her family notices that she sits near the television and often asks "What?" when she is spoken to. Her teachers have indicated that she seems more distractible and is not able to get started on work without direct support. When sent for updated vision and hearing testing, Abigail was found to have a bilateral moderately severe sensorineural hearing loss. Upon review of her early history, it was noted that she had received a broad workup, including an evaluation for congenital infections and genetic syndromes at birth because of microcephaly and small-for-gestational-age growth parameters. Genetic testing had revealed a partial trisomy 9; in addition, her urine culture for cytomegalovirus (CMV) was positive. The critical issue in this case is that while Abigail had received an appropriate evaluation at birth, her partial trisomy had overshadowed the other needs related to her care; therefore, she did not receive the hearing monitoring normally recommended for a congenital CMV infection.

Thought Questions:

How are evaluations of hearing and developmental function made more complex when the child has a disability? What factors contribute to failing to notice hearing loss in children with developmental disabilities?

DEFINITIONS, DESCRIPTIONS, AND CLASSIFICATIONS

In the pursuit of the universal use of respectful and person-first language, it is helpful to begin with an understanding of the Deaf culture. *Merriam-Webster's Dictionary and Thesaurus* (2014) includes a number of definitions of the term *culture*, two of which are the following:

1. The customary beliefs, social forms, and material traits of a racial, religious, or social group; also, the characteristic features of everyday existence (such as diversions or a way of life) shared by people in a place or time.
2. The integrated pattern of human knowledge, belief, and behavior that depends upon the capacity for learning and transmitting knowledge to succeeding generations.

In regard to the Deaf community, shared experiences and a shared language are at the foundation of Deaf culture. Furthermore, most individuals who are D/HH have different experiences than their biologic family (Solomon, 2012). In this way, access to a community with similar experiences strengthens the relevance of cultural affiliation for many individuals.

The affiliation with the Deaf community is conveyed with the capital *D* in Deaf. When the lowercase *d* is used, it is indicative of a degree of hearing loss rather than a cultural affiliation. With this framework, Deafness is not viewed as a disability, but rather a unique way of experiencing the world. It is not a problem to fix or something that is missing. When a person has never experienced the world in any different way, it becomes part of his/her identity. This is different than in people who have had hearing much of their life and lose it. For this group of people, hearing loss is more likely viewed as a problem or disability.

There are a number of resources on Deaf culture that can help in beginning to understand this framework (Holcomb, 2012; Holt & Garey, 2007; Humphries & Padden, 1990). Still, it is important to recognize that not all individuals who are D/HH consider themselves members of the Deaf community. These individuals

may use the term *hard of hearing* (HH) to describe themselves. Individuals who are HH also have common experiences (Holt & Garey, 2007; Zazove, 1993).

This chapter focuses on *Deaf/hard of hearing Plus*, a term used to convey a respectful perspective for those who are D/HH and have developmental or medical complexities. Candace Lindow-Davies, a mother and active advocate within the national organization Hands and Voices (<http://www.cohandsandvoices.org/plus/index.html>) helps frame this definition, noting:

Deaf/HH Plus is meant to be a positive term, not in any way negative or insensitive to the child who has medical issues along with hearing loss. In fact, I see it as an "A+" or "B+," meaning the child carries additional positive qualities. But it is a gift that needs to be carefully unwrapped. And it may not appear to be a gift when you first receive it. Time helps you appreciate, understand and unfold the possibilities. And the "Plus" most often means the child and family has added responsibilities and requires additional expertise. (Lindow-Davies & Kennedy, 2013)

Salient to the discussion of Deaf/HH Plus is the definition of the term *Deaf-blindness*. Deaf-blindness, without explanation, may seem to indicate that a person would have no hearing and no vision. This is not the case. Deaf-blindness is a term that indicates hearing loss of any type or degree and vision impairment that is not correctible. This combination of sensory loss impacts a person's access to communication and learning.

The term *Deaf-blindness* as a label is used to determine service needs across states and educational systems. There is a large discrepancy between census data on Deaf-blindness obtained from U.S. federally funded state Deaf-blind projects and data within special education settings collected by the Office of Special Education Programs (National Center on DeafBlindness, 2016). Data from the 2015 U.S. Department of Education (Office of Special Education Programs 2015 Part B special education child count) identified 1,442 students (3–21 years of age) with an educational category of Deaf-blind. This number is approximately 16% of the 8,979 children (3–21 years of age) identified by the 2016 National Child Center for Deaf-Blindness census.

PREVALENCE AND EPIDEMIOLOGY

D/HH is identified by newborn hearing screening and screening throughout childhood. D/HH occurs at different levels of hearing loss (see Table 26.1). Up to 40%–50% of children who are D/HH have developmental and behavioral needs (Boyle et al., 2011; Chilosi

Table 26.1. Levels of hearing loss by severity

Degree of hearing loss	Hearing loss range (dB HL)
Normal	10–15
Slight	16–25
Mild	26–40
Moderate	41–55
Moderately severe	56–70
Severe	71–90
Profound	91+

From Clark, J. G. (1981). Uses and abuses of hearing loss classification. *ASHA*, 23, 493–500.

et al., 2010; Gallaudet Research Institute, 2011) that are not a direct result of hearing loss. This rate is higher than in the general population (Table 26.2). Conditions and risk factors associated with hearing loss can also be associated with a risk for developmental disabilities. Examples of risk factors for coexisting developmental disabilities and hearing loss include syndromes, congenital infections, and the need for neonatal intensive care (Joint Committee on Infant Hearing, 2007; see Table 26.2).

While the focus of this chapter is on children who are D/HH Plus, it is important to recognize that hearing loss has often been underrecognized in individuals with intellectual disability (Hey et al., 2014; Russ, Kenney, & Kogan, 2013) and other developmental disabilities. Among a large group of participants in the Special Olympics with intellectual disability who received hearing screening, 60% required follow-up and treatment (Hey et al., 2014). While this included middle ear

disease and transient conductive hearing loss, Hey and collaborators noted the importance for ongoing surveillance for fluctuating and progressive hearing loss in children and adults with intellectual disability.

In population data on younger children, Russ and colleagues (2013) performed an analysis of the 2005–2006 National Survey of Children with Special Health Care Needs. Within the cross-sectional data on 40,723 children from birth to 17 years of age, 5% of children with an intellectual disability used hearing aids.

There is limited literature describing hearing loss among children with an autism spectrum disorder (ASD). Population data from the Centers for Disease Control and Prevention identified a rate of hearing loss of 1.3 per 1,000 children with ASD who were 8 years old (Kancherla, Van Naarden Braun, & Yeargin-Allsopp, 2013). A systematic review evaluating the prevalence of hearing loss among children with ASD noted challenges with study methodology, sample sizes, and inclusion criteria (Beers, McBoye, Kakande, Dar Santos, & Kozak, 2014). In the studies included in this systematic review, rates of hearing loss in children with ASD ranged from 0%–10%. It is likely that the rate of hearing loss in the general population would be found among children with ASD. Data from the general population suggest that hearing loss (any degree of permanent hearing loss, unilateral or bilateral) occurs in 1 to 3 out of 1,000 children at birth (Boyle et al., 2011; Centers for Disease Control and Prevention, 2010), with an increase of 6 to 12 per 1,000 school-age children (Goman & Lin, 2016).

In children with ASD, it can be challenging to obtain ear-specific and reliable behavioral audiometric information. Fitzpatrick, Lambert, Whittingham, and Leblanc (2014) described a hospital-based group of children with ASD and hearing loss. For children who had not participated in newborn hearing screening, the age of identification of hearing loss ranged from 16 months to over 7 years. This group had evidence of late-onset and progressive hearing loss. Among children who had newborn hearing screening, the age of identification of hearing loss was between 2 to 12 months. To avoid this delay in identifying a hearing loss, Fitzpatrick and colleagues (2014) suggested pursuing definitive hearing testing with auditory brainstem response if behavioral audiometry is not reliable. Conversely, the presence of hearing loss or D/HH can make it challenging to recognize and definitively identify ASD in a child, prompting relatively late ages of identification of ASD in children who are D/HH (Fitzpatrick et al., 2014; Mandell, Novak, & Zubritsky, 2005; Meinzen-Derr et al., 2014; Mood & Shield, 2014).

Table 26.2. Percent of the types of disabilities in the Deaf/hard of hearing (HH) and general populations

Type of disability	Within deaf/HH	Within general population
No disability	60%	86%
Cognitive (intellectual disability)	8.3%	0.71%
Cerebral palsy and motor disabilities	8%	0.3%
Blindness and vision impairment	5.6%	0.13%
Attention-deficit/hyperactivity disorder	5.4%	7%
Specific learning disability	8%	4.5%
Autism spectrum disorder	1.7%–7%	1.1%

Sources: Boyle et al. (2011); Gallaudet Research Institute (2011); Reid et al. (2011); Szymanski, Brice, Lam, and Hotto (2012); Thomas, Sanders, Doust, Beller, and Glasziou (2015); and Van Naarden et al. (2015).

BOX 26.1 EVIDENCE-BASED PRACTICE**Early Identification of Hearing Loss**

A number of early studies (Kennedy et al., 2006; Moeller, 2000; Yoshinaga-Itano et al., 1998) identified the importance of early identification of hearing loss in infants as important to achieve improved language and developmental outcomes. This work greatly accelerated the adoption of universal newborn hearing screening and prompted the development of the 1-3-6 benchmarks for early hearing detection and intervention programs. Outcome is greatly improved if screening is by 1 month of age, identification of hearing loss by 3 months of age, and intervention by 6 months of age (Joint Committee on Infant Hearing, 2007).

Among children with cerebral palsy, various surveys have estimated hearing loss to occur in 4%–13%, with the most commonly cited rate being 12%. Severe to profound hearing loss has been described to occur in 3%–4% of these children (Dufresne, Dagenais, & Shevell, 2014; Reid, Modak, Berkowitz, & Reddihough, 2011).

In children presenting with developmental disabilities, attention problems, or learning difficulties, it is important to pursue a comprehensive evaluation of hearing (and vision), as unidentified hearing loss can interfere with a child's ability to learn and pay attention. Children with mild hearing loss can have difficulty sustaining attention and experience fatigue from processing spoken instruction in the classroom (Đoković et al., 2014; Porter, Sladen, Ampath, Rothpletz, & Bess, 2013). This challenge can mimic difficulties with inattention, prompting an evaluation for ADHD (O'Connell & Casale, 2005). For example, when a child with a hearing loss does not follow through on instructions, this may be associated with the inability to hear and understand the instructions rather than with an issue with inattention. However, children who are D/HH can also have specific learning disabilities and executive functioning disorders (O'Connell & Casale, 2005). It can be challenging to determine the impact of learning and executive functioning deficits on classroom performance in children who are D/HH (Box 26.1).

Complex medical needs and developmental delays may also contribute to the late identification of hearing loss (Chapman et al., 2011; Fitzpatrick, Cesconetto dos Santos, Grandpierre, & Whittingham, 2017; Box 26.2); children who do not pass newborn hearing screening but have no medical complexities receive a confirmed diagnosis of hearing loss more than 2 months earlier than those with medical complexities.

One important reason for identifying a developmental disability in children who are D/HH is that services would broaden to include approaches and supports for the specific learning or behavioral difficulties. The current system supporting the special education needs of children within Part B programming (Individuals with Disabilities Education Improvement Act of 2004) identifies a primary educational label. This can pose problems for children who are D/HH Plus if teams use the educational label as the primary consideration for goals and services. This may limit access to the full breadth of supports a child may need (Borders, Meinzen-Derr, Embury, Bauer, & Wiley, 2015).

The next section will focus primarily on assessment, but there are inherent risks in misclassification and **diagnostic overshadowing** of developmental disabilities in children who are D/HH. Characteristics of developmental disabilities may be attributed to hearing loss (as seen in children with ADHD), and alternatively,

BOX 26.2 EVIDENCE-BASED PRACTICE**Medical and Developmental Complexities**

Children with medical and developmental complexities face challenges in the early identification of hearing loss, posing further delays to effective interventions to support optimal development (Chapman et al., 2011; Fitzpatrick et al., 2017). Further work is needed to understand how to ameliorate these gaps in the identification and intervention for children who are Deaf/hard of hearing Plus.

characteristics common in children who are D/HH may be viewed as concerning for an atypical learning pattern. These issues can impact accuracy of the epidemiologic data, a common challenge for low-incidence disabilities.

CAUSES AND ASSOCIATIONS WITH SPECIFIC DEVELOPMENTAL DISABILITIES

As noted earlier, there are overlapping risk factors for developmental disabilities and hearing loss (Joint Committee on Infant Hearing, 2007). In some situations, the cause of hearing loss can indicate a risk for developmental disabilities (such as in symptomatic congenital

CMV or in CHARGE syndrome; Ahn & Lee, 2013; see Table 26.3 and Appendix B). In other situations, etiology does not help in understanding the likelihood of developmental concerns beyond that imparted by hearing loss. For example, *GJB2* (connexin) mutations are a common cause of autosomal recessive hearing loss (Gasparini et al., 2000). In early understandings of *GJB2* mutations, it was often reported that children with this genetic etiology of hearing loss were likely to have good developmental outcomes (Sinnathuray et al., 2004). However, over time, reports began to describe children with *GJB2* mutations having coexisting conditions, including other genetic conditions (Kenna et al., 2007; Wiley, Choo, Meinzen-Derr, Hilbert, & Greinwald, 2006).

Table 26.3. Risk factors for hearing loss and known additional developmental risks

Risk factors for hearing loss (Joint Committee for Infant Hearing, 2007)	Known developmental risks beyond hearing loss
NICU stay > 5 days	
ECMO-assisted ventilation	Related to potential CNS injury
Ototoxic medications	Related to underlying condition
Loop diuretics	Related to underlying condition
Hyperbilirubinemia requiring exchange transfusion	Kernicterus
Hypoxic-ischemic events	
In utero infections	<i>Related to underlying conditions:</i>
Cytomegalovirus	(Oliver et al., 2009)
Herpes	(Hermansen & Hermansen, 2006)
Rubella	
Syphilis	
Toxoplasmosis	
Postnatal infections	<i>Related to underlying conditions:</i>
Herpes encephalitis	(Hermansen & Hermansen, 2006)
Bacterial meningitis	
Other acquired causes of hearing loss	
Head trauma	Related to potential CNS injury
Chemotherapy	(Wade, Zhang, Yeates, Stancin, & Taylor, 2016)
	Related to toxic effects on CNS
	(Janzen & Spiegler, 2008)
Craniofacial anomalies	<i>Related to potential syndromes associated with conditions</i>
External ear anomalies	
Temporal bone anomalies	
Cleft lip and palate	
Syndrome involving hearing loss	<i>Specific to syndrome:</i>
Down syndrome	(Brown, Greer, Aylward, & Hunt, 1990)
Neurofibromatosis	(Hyman, Shores, & North, 2006; Nunes & MacCollin, 2003)
Usher syndrome	(Dammeyer, 2012)
Waardenburg syndrome	(Kiani, Gangadharan, & Miller, 2007)
Neurodegenerative disorders	<i>Specific to condition:</i>
Hunter syndrome	(Stapleton et al., 2017)
Sensory motor neuropathies (Freidrich Ataxia, Charcot-Marie Tooth)	(Janzen, Delaney, & Shapiro, 2017; Reetz et al., 2016)
	(Cornett et al., 2016;
	Corrado, Ciardi, & Bargigli, 2017)

Key: ECMO, extracorporeal membrane oxygenation.

The co-occurrence of two or more conditions suggests that identifying a known etiology for hearing loss does not protect a child from the presence of other genetic conditions or environmental risks that contribute to the emergence of developmental disabilities.

The coexistence of developmental disorders (such as intellectual disability, ASD, and multiple congenital anomalies) in children who are D/HH is particularly pertinent to the practice of developmental-behavioral pediatrics (see Table 26.4). Focusing only on the hearing loss in the context of the genetic workup in children with developmental disabilities could miss the contribution of other genetic conditions. Developmental-behavioral pediatricians and geneticists are in a position to recognize when a broader genetic workup is indicated. It is appropriate to apply current genetic guidelines for the developmental condition in the general population (Miller et al., 2010) to children who are D/HH when indicated.

DIAGNOSIS AND CLINICAL MANIFESTATIONS

Diagnostic considerations must take into account a recognition of the impact of a child's degree of hearing loss on access to language. Families are faced with making decisions regarding communication approaches early in the time frame of identification of their child's hearing loss. These decisions can include auditory, visual, and/or tactile means (in the case of children who are Deaf-blind). Families experience varying opinions and

information related to these decisions (Crow et al., 2014; DesGeorges, 2016; Kushalnagar et al., 2010). As young children grow and develop, differences in language processing may become evident, prompting changes in approaches to building communication skills (Putz, 2012).

Appropriate Language Expectations

In children who have had the benefit of early identification and intervention for hearing loss, slow language development as a result of hearing loss should not be considered the norm (Meinzen-Derr et al., 2018; see Box 26.3). Children who receive intervention prior to 6 months of age can achieve language levels within the average range of the general population (Kennedy et al., 2006). Yoshinago-Itano, Sedey, Coulter, and Mehl (1998) found that children identified prior to 6 months of age had language quotients just under 90 compared to a language quotient of approximately 70 for children identified after 2 years of age. Moeller (2000) found a similar impact on receptive vocabulary development, with average standard scores (population mean scores of 95) for children enrolled early in services. This is in distinct contrast to substantially below-average language standard scores (population mean scores of 70) for children who enrolled in services after 35 months of age.

While the attainment of average language abilities among early-identified children who are D/HH seems quite positive, it is imperative to also consider the nonverbal cognitive capabilities when focusing on language development. Children with low-average language skills actually could be exhibiting language underperformance when taking into account their nonverbal cognitive potential (Meinzen-Derr et al., 2014; Meinzen-Derr et al., 2018).

If a child who is D/HH is not making appropriate language progress, there may be a number of contributing factors. No matter what the communication modality chosen (auditory/oral or sign language systems), it is important to have strong access to language information and a language-rich environment.

Table 26.4. Percent of population with hearing in populations with specific disabilities

Disability	Estimates of percentage of the population with hearing loss
Intellectual disability	5%
Autism spectrum disorder	0.1%
Cerebral palsy	4%–13%

BOX 26.3 EVIDENCE-BASED PRACTICE

Co-occurrence of Developmental Disabilities

The co-occurrence of a developmental disability in children who are Deaf/hard of hearing (D/HH) is commonly discussed in the literature and supported by existing surveillance systems (Boyle et al., 2011; Chilosi et al., 2010; Gallaudet Research Institute, 2011). This literature suggests a need for a high level of suspicion if a child who is D/HH is not making anticipated developmental progress.

For an auditory/oral approach, it is foundational to have consistent acoustic access through technology (i.e., hearing aids and cochlear implants). Communication environments may need adaptations to ensure that the child is able to have acoustic access to support language development. These adaptations can include addressing the impact of the distance of the speaker to the child and the amount of background noise. Regular technology checks are important, and early recognition of progressive hearing loss can ensure amplification is adjusted accordingly (Barreira-Nielsen et al., 2016).

In families selecting a signing approach, the language competence of those around the child is critical to ensure strong language modeling for supporting language development. When access to language and the rigor of therapeutic interventions are not of concern, but the child is not making expected language progress, there may be the presence of a broader developmental disability or language disorder.

General Assessment Considerations

Assessment of the development of children who are D/HH requires some adaptations and special considerations for testing batteries (Marschark, 2003). Additional factors are also important to consider, including the communication skills of the child, the ability of the clinician to communicate directly with the child, the need and role for an interpreter, and the goals of the evaluation (Reesman et al., 2014).

When possible, evaluators should have a general knowledge of typical development among children who are D/HH (Box 26.4). This allows a context for recognition of atypical learning or behavioral concerns. When this is not possible, partnerships and communication with professionals knowledgeable in deafness can allow for discussions about a specific child's profile; what factors, behaviors, or characteristics could be related to hearing loss; and what may indicate a broader developmental concern.

When assessing/evaluating children who are D/HH and are developing differently, it is helpful to consider

how a child accesses and processes information best. There are also situations when a child's "input" for communication and information differs from their preferred "output." For example, children who have good access to sound through amplification may understand spoken language well, yet due to motor difficulties with speech or the presence of a tracheostomy tube, expressive language may be best produced through sign language or the use of technology. In these circumstances, exposing children to the "output" modality is critical to allow continued expressive language growth.

Within the field of complex developmental disabilities, assessment batteries may require adaptations (Goodman, Evans, & Loftin, 2009; National Institutes of Health, 2012; NINDS, 2018). Meaningful information can be elicited from a variety of settings with multiple perspectives (parents, teachers, or therapists). Qualitative information may be more salient than standardized test scores when developing an intervention approach (Box 26.5). For children who are Deaf-blind, specialized expertise is essential in guiding meaningful assessment (National Consortium on Deaf-Blindness, 2009).

Cognitive Abilities It can be helpful to frame an understanding of cognitive development in children who are D/HH by separating the assessment of language from language-based reasoning and focusing on nonverbal reasoning skills. The lack of inclusion of children who are D/HH in normative samples during the development of an assessment tool can limit their utility in children who are D/HH (Reesman et al., 2014). Reesman and colleagues (2014) described various cognitive assessments with guidance on the need for accommodations, interpretation, normative sampling, and potential biases. Tools described include the Bayley Scales of Infant and Toddler Development, Third Edition (Bayley, 2006); the Stanford-Binet Intelligence Scales, Fifth Edition (Roid, 2003); the Leiter International Performance Scale-Revised (Roid & Miller, 1997), the Wechsler Preschool and Primary Scale of Intelligence, Fourth Edition (Wechsler, 2003b);

BOX 26.4 INTERDISCIPLINARY CARE

Importance of Interdisciplinary Team Work for Children Who Are Deaf/Hard of Hearing Plus

A strong and diverse interdisciplinary team is particularly important for assessing children who are Deaf/hard of hearing (D/HH) with a potential developmental disability. A strong understanding of the usual developmental patterns in typically developing D/HH helps team members recognize when a child may be learning and progressing differently.

BOX 26.5 INTERDISCIPLINARY CARE**Importance of Multiple Sources of Information and Perspectives
When Considering the Needs of Children Who Are Deaf/Hard of Hearing Plus**

Blending expertise from various areas including parents, teachers, interpreters, audiologists, clinicians with expertise in the evaluation and management of children who are Deaf/hard of hearing (D/HH), and clinicians with expertise in the evaluation and management of developmental disabilities will enhance the understanding of a child who is D/HH with a complex learning pattern. With this approach, broader intervention approaches can be implemented, allowing a child who is D/HH Plus the opportunity to make developmental progress.

the Differential Abilities Scales, Second Edition (Elliot, 2007); the Kaufman Assessment Battery for Children, Second Edition (Kaufman & Kaufman, 2004); the Reynolds Intellectual Assessment Scales (Reynolds & Kamphaus, 1998); the Wechsler Nonverbal Scale of Ability (Wechsler & Naglieri, 2006); the Wechsler Intelligence Scale for Children, Fourth Edition (Wechsler, 2003a), the Comprehensive Test of Nonverbal Intelligence (Hammill, Pearson, & Wiederholt, 2009); and the Universal Nonverbal Intelligence Test (Bracken & McCallum, 2016; see Chapter 13).

Autism Spectrum Disorder When evaluating children who are D/HH for ASD, it is important to have a standardized approach that takes into consideration the core features of this social-communication disorder. However, autism-specific assessment tools are very limited regarding validation in children who are D/HH (Mood & Shield, 2014).

ASD symptoms in children who are D/HH may be difficult to categorize on some tools. For example, a child who is D/HH with ASD may not respond to his/her name when called. If the child has amplification and can respond to quiet environmental sounds and the evaluator does not take into consideration the child's ability to perform this skill, this lack of response may be incorrectly ascribed to hearing loss when, in fact, it is due to an ASD. Adaptations may also be required to assess this core social communication. In children who sign, there are ways to gain attention that are different than calling out a name. Responsiveness to these typical strategies, however, can be limited in deaf children with ASD. Atypical language features are evident in children who are D/HH with ASD, such as echolalia in sign language (Shield, Cooley, & Meier, 2017).

Unfortunately, the gold-standard autism assessments, such as the Autism Diagnostic Observation Schedule (Lord et al., 2012); the Autism Diagnostic

Interview-Revised (Lord, Rutter, & Le Couteur, 1994), the Childhood Autism Rating Scale (Schopler, Van Bourgondien, Wellman, & Love 2010), the Gilliam Autism Rating Scale (Gilliam, 1995), and the Autistic Behavior Checklist (Krug, Arick, & Almond, 1993), have not been normed or validated in children who are D/HH. Despite these limitations, these tools have been used in describing children who are D/HH and have been diagnosed with ASD (Johansson, Gilberg, & Rastam, 2010; Jure, Rapin, & Tuchman, 1991; Meinzen-Derr et al., 2014; Mood & Shield, 2014; Roper, Arnold, & Monteiro, 2003).

The optimal approach for assessing children who are D/HH and have ASD is to employ a professional trained both in hearing loss and ASD and who can communicate directly with the child irrespective of communication modality. However, meeting this best practice would markedly limit access to assessment. Including professionals knowledgeable in children who are D/HH in the assessment of ASD is encouraged (Szarkowski, Mood, Shield, Wiley, & Yoshinaga-Itano, 2014). When needing to rely on sign language interpreters to facilitate communication, using an interpreter who is familiar with the child's language (such as a school interpreter) and preparing the interpreter with what is needed in the assessment has been a strategy some have used (Szarkowski et al., 2014). The role of interprofessional collaboration cannot be understated in these situations.

Deaf-Blind Children with Deaf-blindness are best assessed through a highly collaborative interdisciplinary team, highlighting a child's functional skills across many domains. Understanding a child's functional vision allows for appropriate visual and tactile adaptations in assessment materials and the testing environment. It is also critical to understand how a child with Deaf-blindness communicates and to have the ability to interpret and respond to the child's communication

(Goodman et al., 2009; National Consortium on Deaf-Blindness, 2009; Riggio & McLetchie, 2008). Each state has a federally funded Deaf-blind project that is a good starting resource for expertise in understanding the complexities of children with Deaf-blindness.

MONITORING, SCREENING, AND EVALUATION

There is a paucity of evidence to guide the use of screening tools to identify developmental difficulties in children who are D/HH. However, it is important to implement ongoing monitoring of progress and recognize when a child is not meeting developmental milestones or when trajectories are diverting from the expected (Wiley & Meinzen-Derr, 2013; Yoshinaga-Itano, Baca, & Seday, 2010; Yoshinaga-Itano, 2014).

Furthermore, as the initial case illustrates, it is important to monitor hearing and vision in children with known developmental disabilities. Continued research in these areas is critical to improve our current approaches to effectively identify developmental disabilities in children who are D/HH and identify hearing loss in children with an existing developmental disability (Chen et al., 2014).

TREATMENT, MANAGEMENT, AND INTERVENTIONS

When considering treatment, management, and interventions for children who are D/HH Plus, the approach to supporting needs related to hearing is not necessarily different than in children who are D/HH (Fitzpatrick et al., 2014; Tharpe, Fin-Szumski, & Bess, 2001). There may be aspects of a specific child's needs that require adaptations to amplification, cochlear implantation, and therapeutic and educational interventions. For example, in a child with cerebral palsy who uses a wheelchair for mobility, positioning may impact the ease of keeping a cochlear implant in place. Families of children who are D/HH with complex needs have indicated an appreciation of access to intervention for hearing (Wiley, Jahnke, Meinzen-Derr, & Choo, 2005). Treatment decisions for a child's specific hearing pattern can be discussed with the family to guide how to apply best available evidence and practice guidelines.

There may be some unique considerations in children who are medically complex. For example, surgical risks, need for ongoing central nervous system imaging, and complex inner ear malformations may contribute to decisions specific to cochlear implantation and other surgically implanted devices (i.e., bone-anchored hearing aids and auditory brainstem implants; Doshi,

Schneiders, Foster, Reid, & McDermott 2014; O'Brien et al., 2010; Sennaroğlu et al., 2016). Families and professionals alike are faced with limited outcome data to guide decision making.

Evidence-based treatment options for children who are D/HH Plus are very limited. Traditional interventions used within the field of developmental disabilities that are applied to children who are D/HH Plus are found in only very small case reports. Reports of using the Picture Exchange Communication System (Malandraki & Okalidou, 2007), video modeling (Thrasher, 2014), and augmentative and alternative communication (Lee, Jeong, & Kim, 2013; Meinzen-Derr, Wiley, McAuley, Smith, & Grether, 2017) approaches have been described. Despite the limited evidence in the field, these approaches to build communication in children who are D/HH Plus show promise.

Family-to-family support is important for all families of children who are D/HH and for families of children with developmental disabilities. Due to the unique combination of complexities, it can be challenging to identify mechanisms to meaningfully provide this support for children with D/HH Plus (Myck-Wayne, Robinson & Henson, 2011; Wiley, Gustafson, & Rozniak, 2014).

OUTCOMES

Within the existing literature, there have been two main approaches to understanding outcomes in children who are D/HH Plus. Some authors have described groups of children who are D/HH with a variety of developmental disabilities (cross-categorical), while others have focused on subpopulations of children (i.e., ASD, CHARGE syndrome, or Deaf-blind). The topic of children who are D/HH with ASD is relatively common within the literature. Despite interest in the topic, however, the level of evidence tends to be at a case-description or case-series level, frequently using retrospective chart reviews. Authors rarely describe severity levels or consider the presence of coexisting disabilities, such as an intellectual disability, that could impact language and speech outcomes.

For some coexisting conditions, it is difficult to find specific papers by using a typical query of the literature. A reader may uncover the existence of children with various disabilities (e.g., apraxia of speech within children who are D/HH) when reading the inclusion section of a study and looking at who has been excluded from the analysis. Furthermore, cognitive abilities are often not included in the description of populations of children who are D/HH, prompting difficulties in understanding the complex interplay of disabilities and the impact on specified outcomes.

A limitation of the existing knowledge is the tendency for the literature to compare children who are D/HH Plus with typically developing peers who are D/HH rather than with disability matched or cognitively matched peers (Meinzen-Derr, Wiley, Grether, & Choo, 2011). This poses challenges in guiding families on what to expect related to language and developmental outcomes. Many papers state in their conclusion section that children who are D/HH Plus with implants make progress but at a slower rate than typically developing D/HH children.

Centers vary in their interpretation of outcomes and level of enthusiasm for pursuing specific interventions (i.e., cochlear implantation). In general, reports have described lower long-term adherence with cochlear implant use in children with ASD (Valero et al., 2016) and developmental disabilities (Özdemir et al., 2013) as compared to typically developing implant users. Speech perception and auditory performance among children with disabilities who use cochlear implants have also been described. Some authors have found improvements in objective measures of speech perception, auditory performance, and language skills but at a slower rate and level than typically developing children with implants (Birman, Elliott, & Gibson, 2012; Cruz, Vicaria, Wang, Niparko, & Quittner, 2012; Eshraghi et al., 2015; Mikic et al., 2016).

Within the broader group of children who are D/HH Plus who do not use cochlear implants, early childhood outcomes have been described. In a relatively large group of 119 children with hearing loss and additional disabilities, outcomes were affected by the type of disability (i.e., autism, cerebral palsy, and developmental delay), and level of maternal education affected speech, language, and functional auditory skills (Cupples et al., 2014). They noted that when conditions were not associated with a developmental delay or ASD, outcomes were better predicted by the coexisting condition than by the degree of hearing loss. In addition, a number of authors describe the importance of considering different outcomes, particularly functional and quality-of-life considerations for children who are D/HH Plus (Berrettini et al., 2008; Cejas, Hoffman, & Quittner, 2015; Edwards, Hill, & Mahon, 2012; Wiley et al., 2005; Zaidman-Zait, Curle, Jamieson, Chia, & Kozak, 2015).

Work with children who are D/HH Plus can present multiple and competing priorities. Families serve as the compass to guide priorities and service delivery models. Building effective teamwork with professionals from a variety of backgrounds and expertise can allow for effective adaptations of intervention strategies to improve a child's outcomes. Using a strengths-based approach is critically important in children who are D/HH and D/HH Plus.

SUMMARY

- Children who are D/HH are at higher risk for developmental disabilities than the general population.
- Children with language delays and developmental disabilities should have hearing and vision evaluated due to risks for sensory impairments.
- The workup in children who are D/HH Plus should include both a hearing-targeted assessment and broader genetic testing based on current guidelines for developmental disabilities.
- Irrespective of communication modality, when children who are D/HH lag behind in their language development, broader developmental concerns should be considered.
- Assessing the breadth of developmental needs in children who are D/HH is enhanced by cross-disciplinary communication and team work.

CHAPTER 27

Behavioral and Psychiatric Disorders

Adelaide S. Robb and Gabrielle Sky Cardwell

Upon completion of this chapter, the reader will

- Understand that individuals with developmental disabilities have a relatively high prevalence of psychiatric disorders
- Be able to describe the types and symptoms of psychiatric disorders among people with developmental disabilities
- Be able to discuss interventions in children who have a dual diagnosis of a developmental disability and a psychiatric disorder

Children with developmental disabilities manifest the same range of psychiatric illnesses that typically developing children do, but they may also face psychiatric illnesses specific to their disorder. The presence of a developmental disability, especially intellectual disability, often alters the symptomatic presentation of psychiatric disorders and makes accurate diagnosis more difficult. Recognition of these problems in children with **dual diagnoses** (a developmental disability and a psychiatric disorder) is crucial for caregivers. When these psychiatric disorders go unrecognized or untreated, affected children can fail in educational and social settings, engage in challenging behaviors at home, and show aggression and self-injury. These comorbid conditions may ultimately determine the child's outcome and placement. Notably, individuals with developmental disabilities who exhibit challenging behaviors such as aggression and self-injury are more likely to have a comorbid psychiatric disorder (Grey, Pollard, McClean, MacAuley, & Hastings, 2010). If the condition is identified early, however, treatment can be started and long-term adverse effects minimized.

It is a challenge for parents and individuals working with children with developmental disabilities to be alert to the possible presence of a psychiatric disorder and obtain early assessment, diagnosis, and treatment. This chapter addresses the identification and treatment of behavioral and psychiatric disorders in children with disabilities; it also discusses developmental transitions and their effect on behavior.

■ ■ ■ CASE STUDY

Gregory, age 17, has high-functioning autism spectrum disorder (ASD), attention-deficit/hyperactivity disorder (ADHD), and generalized anxiety disorder (GAD). He is in a special educational setting for high school students with high-functioning ASD and attends a special academy for culinary students as part of his academic day. He is being treated with an **antipsychotic medication** (aripiprazole), an antidepressant (bupropion), and a **stimulant** (methylphenidate). He has been stable for a long period with resolution of his previous psychiatric symptoms. The family has been concerned about his

weight, which has increased above a BMI of 30 primarily due to excessive eating despite frequent exercise. In consultation with the family, the child psychiatrist began slowly tapering off the antipsychotic medication, which can cause overeating, over a 3-month time period. Once he was off the antipsychotic medication, his psychiatric condition deteriorated. He became irritable and easily angered. He was aggressive at home, with classmates, and with teachers. The school and parents consulted with the psychiatrist, who restarted Gregory on aripiprazole and titrated the dose back up to his prior dose with rapid resolution of his symptoms. He was back to being himself by the end of the second week on aripiprazole. His parents and therapy team are now evaluating other approaches to weight control.

Thought Questions:

At what ages (e.g., preschool age, school age, and adolescence) do the different types of behavioral and psychiatric disorders typically appear or are diagnosed? For the three disorders of interest, what are the main categories of intervention?

PREVALENCE OF PSYCHIATRIC DISORDERS AMONG CHILDREN WITH DEVELOPMENTAL DISABILITIES

In their landmark study of the epidemiology of childhood psychiatric disorders on the Isle of Wight, Rutter, Graham, and Yule (1970) found emotional disturbances in 7%–10% of typically developing children. In contrast, 30%–42% of children with intellectual disability demonstrated psychiatric disorders (Rutter et al., 1970). In a Swedish study, Gillberg et al. (1986) found that 57% of children and adolescents with mild intellectual disability and 64% with severe intellectual disability met diagnostic criteria for a psychiatric disorder. Additional studies have confirmed these results; children with intellectual disabilities have a four- to five-fold higher rate of psychiatric disorders than typically developing peers, and that higher rate does not diminish as the children grow into adolescence (Howlett, Florio, Xu, & Trollor, 2015).

In examining specific neurodevelopmental disorders, it is apparent that patients can have different rates of psychiatric disorders depending on their diagnosis (see Table 27.1). In children with velocardiofacial syndrome (22q11.2 deletion syndrome), the most common behavioral/psychiatric disorders are ADHD (25%–46%); major depressive disorder (12%–20%); and anxiety

disorders, including specific phobias (27%–61%; Arnold, Siegel-Bartelt, Cytrynbaum, Teshima, & Schachar, 2001). In adults with 22q11.2 deletion, 32% experienced psychotic symptoms and 41% had depression (Schneider et al., 2014; Swillen & McDonald-McGinn, 2015; Tang et al., 2014). Both boys and girls with fragile X syndrome have higher rates of social anxiety than typically developing peers. Affected girls have higher rates of depression and affected boys have higher rates of aggression (Gross, Hoffmann, Bassell, & Berry-Kravis, 2015; Powis & Oliver, 2014). In children with fragile X syndrome, the rates of anxiety were reported to be as high as 42% when teachers were asked to rate symptoms; parents noted anxiety in 26% of the same children (Sullivan, Hooper, & Hatton, 2007). In girls with fragile X syndrome, the rates of mood disorders were found to be 47%, with major depression representing half of those disorders (Freund, Reiss, & Abrams, 1993). Boys with fragile X syndrome were found to have high rates of manic/hyperactive behaviors, but low rates of depressed mood based on maternal report (Thurman, McDuffie, Hagerman, & Abbeduto, 2014). Rates of bipolar disorder, however, are lower in children with fragile X than in the general population (Hessl et al., 2001). Up to 70% of boys with fragile X syndrome can exhibit self-injurious behavior (SIB; Hall, Barnett, & Hustyi, 2016; see Chapter 15).

Children with trisomy 21 (Down syndrome) have increased rates of behavioral disorders; 20%–40% exhibit aggression and ADHD versus 5%–8% ADHD in typically developing children. Adolescents with trisomy 21 also have increased rates of unspecified psychosis or depression with psychotic features (43% versus 13%) compared to adolescents with other intellectual disorders (Dykens et al., 2015). Adults are at increased risk for dementia and withdrawal depression compared with typically developing adults (Dekker et al., 2015; Esbensen, Johnson, Amaral, Tan, & Macks, 2016; Lautarescu, Holland, & Zaman, 2017; Määttä, Tervo-Määttä, Taanila, Kaski, & Iivanainen, 2014; McCarron, McCallion, Reilly, & Mulryan, 2014). In trisomy 21, conduct disorder (CD) and oppositional defiant disorder (ODD) occur at comparable rates with the general population (12%), whereas autism occurs in about 10% versus a little more than 1% in the general population (Lott, 2012; see Chapter 15).

In children with Prader-Willi syndrome, the occurrence of obsessive-compulsive disorder (OCD) symptoms varies according to the molecular defect. Individuals with long type I 15q deletions have compulsive cleaning (e.g., grooming and showering), whereas those with short type II 15q deletions have academic OCD symptoms (e.g., rereading, erasing, and counting; Zarccone et al., 2007). Prader-Willi is also associated

Table 27.1. Percentages of mental illness by developmental disability

Population	MI	ADHD	ODD	CD	MDD	BPD	SZ/PSY	AXD	PH	GAD	SIB	ASD

XXYY					50							
FAE				50		33–35						
FAS					18	33–35						
WS	80	65							54	12		

Key: DD, developmental disability; ID, intellectual disability; VCF, velocardiofacial syndrome; FRX, fragile X syndrome; TR21, trisomy 21; PWS, Prader-Willi syndrome; TS, Turner syndrome; FAE, fetal alcohol exposure; FAS, fetal alcohol syndrome; WS, Williams syndrome; MI, mental illness; ADHD, attention-deficit/hyperactivity disorder; ODD, oppositional defiant disorder; CD, conduct disorder; MDD, major depressive disorder; BPD, bipolar disorder; SZ/PSY, schizophrenia/psychotic disorder; AXD, anxiety disorder; PH, phobia; GAD, generalized anxiety disorder; SIB, self-injurious behavior; ASD, autism spectrum disorder; SP, social phobia.

with higher rates of bipolar disorder (15%–17% versus 2%–5% in the typically developing population) and mood disorders (with psychotic features occurring in 28% versus 0.4% in the general population; Butler, Manzardo, & Forster, 2016; Skokauskas, Sweeny, Meehan, & Gallagher, 2012). Adolescents with Turner syndrome have high rates of social phobia, shyness, anxiety, and depression, with anxiety and mood swings becoming evident in adulthood (Saad et al., 2014; Saad, Al-Atram, Baseer, Ali, & El-Houfey, 2015). Almost half of individuals with XXYY syndrome have major depression and are at an increased risk for ADHD (Tartaglia, Ayari, Hutaff-Lee, & Boada, 2012).

In children who have prenatal exposure to alcohol but without features of fetal alcohol syndrome (FAS; see Chapter 2), rates of CD are as high as 50% (Burd, Klug, Martsof, & Kerbeshian, 2003). For children with FAS, both suicide and depression rates are elevated. Up to half attempt suicide, and major depression is found in approximately 18% of those exposed to alcohol in utero (Burd et al., 2003; O'Connor et al., 2002). For those with fetal alcohol spectrum disorder (including both FAS and prenatal alcohol exposure), rates of bipolar disorder range from 33%–35% (O'Connor et al., 2002). CD and ADHD are also common among these individuals, with pooled prevalence rates of 90.7% and 51.2%, respectively (Popova et al., 2016).

In a comprehensive study of children with Williams syndrome, 80% were found to have one or more psychiatric disorders, the most common being ADHD (65%), followed by specific phobia (54%) and then GAD (12%) (Leyfer, Woodruff-Borden, Klein-Tasman, Fricke, & Mervis, 2006). Recent reviews have also found a high prevalence of anxiety in these individuals (Dankner & Dykens, 2012; Riby et al., 2014; Stinton, Tomlinson, & Estes, 2012; Young, Apfeldorf, Knepper, & Yager, 2009).

CAUSES OF PSYCHIATRIC DISORDERS IN DEVELOPMENTAL DISABILITIES

Children with developmental disabilities are at risk for the same types of psychiatric disorders as typically developing children. In addition, certain maladaptive behavior disorders are found principally among individuals with severe to profound levels of intellectual disability. These behaviors include stereotypic movement disorder (i.e., repetitive, self-stimulating, non-functional motor behavior, which may include SIB) and pica (i.e., the persistent ingesting of nonfood items).

In some cases, the cause of a psychiatric disorder in individuals with developmental disabilities is the direct result of a biochemical or genetic abnormality (see Box 27.1). For example, in the inborn error of

BOX 27.1 EVIDENCE-BASED PRACTICE**Genetic Testing to Detect Developmental Disorders**

Genetic testing can be used to detect and diagnose developmental disorders in children. For example, fluorescence in situ hybridization was one of the first methods of genetic testing used to diagnose 22q11.2 deletion syndrome. This targeted testing method also led to the discovery that many syndromes previously thought to be unrelated conditions, such as velocardiofacial syndrome, also resulted from 22q11.2 deletion (Driscoll et al., 1993). In recent years other genetic tests have been found effective in detecting 22q11.2 deletion syndrome, such as chromosomal microarray analysis (Lu et al., 2008) and multiplex ligation-dependent probe amplification (Schouten et al., 2002).

metabolism Lesch-Nyhan syndrome (see Appendix B), an abnormality in the dopamine neurotransmitter system causes affected individuals to exhibit a compulsive form of SIB (Mohapatra & Sahoo, 2016; Tewari, Mathur, Sardana, & Bansal, 2017). In other cases, conditions that affect the developing brain are risk factors for a psychiatric disorder. For instance, in 1956, Pasamanick, Rogers, and Lilienfeld hypothesized that prenatal brain injury and exposure to toxins during pregnancy could cause behavior disorders in children. In the years since, several studies have linked prenatal alcohol, tobacco, illicit drug, and chemical exposure to the development of neuropsychological disorders in children. Such studies have been important in identifying and eliminating a potential cause of developmental and psychiatric disorders in children.

In addition to fetal alcohol and drug exposure, congenital infections such as rubella (which is associated with ASD) and perinatal or neonatal hypoxic ischemic encephalopathy (brain disorders due to lack of oxygen or blood flow) are associated with memory and language disorders (see Chapter 17). The increased risk of psychiatric disturbance due to neurobiological disorders may be attributable to factors such as irritability, affective instability, distractibility, and communication impairments (Feinstein & Reiss, 1996). Risks may also increase in the presence of conditions such as epilepsy, developmental language disorders, and sensory impairments, which are independently associated with an increased incidence of psychiatric disorders (Salmon, O'Kearney, Reese, & Fortune, 2016; Van Ool et al., 2016; Van Tricht et al., 2015).

The cause of most psychiatric disorders among children with developmental disabilities is likely to be a complex interaction among biological (including genetic), environmental, medical, and psychosocial factors. For example, a young man who has sustained a significant traumatic brain injury (see Chapter 23) with resulting cognitive impairment may regularly become depressed because of a combination of neurotransmitter

changes due to brain injury, a familial predisposition to depression, his parents' grief, and his own despair over loss of previous abilities. Children with severe intellectual disability may develop SIB in response to an ear infection or constipation as they cannot verbally express feeling discomfort.

PSYCHIATRIC DISORDERS OF CHILDHOOD AND ADOLESCENCE

The following sections discuss a number of psychiatric disorders; however, two important disorders, ASD and ADHD, are not discussed here because separate chapters are devoted to them (see Chapters 18 and 19). It should be noted that in the *Diagnostic and Statistical Manual—Fifth Edition (DSM-5)*, the American Psychiatric Association (APA, 2013) has proposed several criteria changes for diagnosing a number of disorders covered in this section. These are described as follows: Post-traumatic stress disorder (PTSD) in children needs only two symptoms of negative alterations in cognition and mood and two symptoms in arousal and reactivity. The trauma can be the loss of a parent and can manifest as nonspecific frightening dreams, themes of trauma in play, or reenactment of the trauma. In pediatric eating disorders, less emphasis is placed on the strict diagnostic requirement of being less than 85% of ideal body weight and having amenorrhea. The criteria now focus on previous weight and growth patterns and the impact of starvation on multiple organ systems, not just the reproductive system. A new disorder in children under consideration in *DSM-5* is disruptive mood dysregulation with dysphoria, which is considered a milder condition than the classic combined ODD and bipolar disorder. This proposed disorder describes children with persistent negative mood who have outbursts of rage. Changes to other disorder criteria in *DSM-5* are described in the following sections.

Oppositional Defiant and Conduct Disorders

In order for a child to be diagnosed with ODD, there must be a pattern of negative, hostile, and defiant behaviors (APA, 2013). Children must have angry/irritable moods, defiant/headstrong behaviors, and vindictiveness. In terms of the persistence and frequency used to differentiate normative and symptomatic behavior, there are different standards for children by age. Children younger than age 5 should show these behavior problems most days for at least 6 months, whereas children who are older than age 5 years should show such problems at least once a week for at least 6 months. Developmental level, gender, and culture must also be considered in making the diagnosis. Further, these behaviors must occur outside of a psychotic or mood disorder. They must cause impairments in social, educational, or vocational activities and may occur in one or multiple settings. This diagnosis is usually given to preadolescent children.

To be diagnosed with a CD, an individual must demonstrate a pattern of callous and unemotional behavior in which other people's rights are violated, norms are ignored, or rules are broken, and it must have continued for at least 12 months. The four main problem areas are 1) aggression toward people and animals, 2) destruction of property, 3) deceitfulness or theft, and 4) serious violation of rules. Some examples of aggression include bullying and threatening, starting physical fights, using a weapon in fights, being physically cruel to people or animals, stealing while confronting a victim, and forcing someone into unwanted sexual activity. Destruction includes deliberate fire-setting or vandalism or destruction of property. Deceitfulness or theft includes breaking into a house or car, lying to obtain goods or services, and stealing or shoplifting. Serious violation of rules includes staying out at night (but not overnight) before age 13, running away from home overnight at least twice, and frequent truancy from school before age 13. CDs are rarely diagnosed in preadolescent children. If a child meets criteria for CD, he or she does not receive a concurrent diagnosis of ODD. Both ODD and CD occur at higher rates in children with developmental disabilities than in typically developing children, 48% overall versus 6%–10% ODD and 2%–9% CD in typically developing populations (Hardan et al., 1997). It should be noted that children with an intellectual disability and ADHD have higher rates of ODD and CD than children with ADHD alone (Ahuja, Martin, Langley, & Thapar, 2013).

ODD and CD are often associated with ADHD, and the treatment for one may improve the condition of the other (Kutcher et al., 2004). Treatment of both CD and

ODD includes the same behavior management techniques useful in ADHD. Similarly, both disorders may benefit from stimulant and other ADHD medications (Connor, Barkley, & Davis, 2000). Among the latter medications are 1) atomoxetine (Strattera), a norepinephrine reuptake inhibitor that is effective at higher doses for children and adolescents with ADHD comorbid with ODD or CD (Newcorn, Spencer, Biederman, Milton, & Michelson, 2005), and 2) long-acting guanfacine, an α -2 receptor antagonist, which also helps control ADHD with comorbid ODD/CD (Connor et al., 2010). A long-acting form of clonidine, another α -2 receptor antagonist, is now approved for ADHD monotherapy in 6–17 year olds (Jain, Segal, Kollins, & Khayrallah, 2011).

Although all categories of ADHD medication (stimulants, norepinephrine reuptake inhibitors, and α -2 receptor agonists), can help when ADHD is comorbid with ODD/CD, behavioral therapy is the preferred treatment for ODD and CD. Behavioral therapy involves setting consistent limits, behavioral expectations, and consequences (see Chapter 34). This intervention must be consistent at home and school so that the child knows that the rules and expectations are enforced in all settings. For younger children, a positive reinforcement system employing stickers and/or a behavior chart to target being respectful and following directions can cover most daily rules and activities. For older children and adolescents, tokens are commonly used to reinforce appropriate behavior. These can be traded for desired activities, such as an extra 30 minutes of television or free computer time. In this way, adolescents earn and pay for their privileges in the same way that adults earn money to buy what they need or want. Evidence-based treatments for CD often include multisystemic therapy (Henggeller et al., 1986) and wrap-around services (Burchard, Bruns, & Burchard, 2002). Both treatments are family focused and offer children support and services in their home, school, and community in order to improve behavior (Suter & Bruns, 2009; Weiss et al., 2013). In this way, treatment not only targets the child's behavior, but also the behavior of his or her peers, family, and even those in other networks, such as his or her school, to offer a more holistic, multi-domain approach to treatment.

Impulse Control Disorders

Impulse control disorders include intermittent explosive disorder and hair-pulling disorder. Intermittent explosive disorder is diagnosed after several discrete episodes of failure to resist aggressive impulses, with resultant assaults or destruction of property. The severity of the assault must be out of proportion to the precipitating psychosocial stressor. An example might be

a child who is told that he cannot have cake until he has finished his lunch. The child then throws his plate across the room, breaks his chair, and starts kicking his little sister over the incident. Treatment of intermittent explosive disorder in adults includes the use of beta-blockers such as propranolol, certain antiepileptic/mood stabilizing drugs (e.g., valproic acid), and novel antipsychotics (e.g., risperidone; Hässler & Reis, 2010). Children with mild to moderate intellectual disability are more likely to have this disorder than their typically developing peers.

An individual fits the profile for hair pulling disorder, historically called trichotillomania, when it results in noticeable hair loss; this can be anywhere on the body. It should not be associated with an underlying skin or physical condition causing hair loss. Consultation with a dermatologist to rule out skin problems such as tinea capitis (ringworm), which can cause hair loss, may be appropriate. A child with this disorder feels tension that makes the child pull out the hair, which is followed by a sense of relief after doing it. Children who have hair pulling disorder may eat the hair, which can cause bezoars (hair balls) in the stomach or gastrointestinal track that need to be surgically or endoscopically removed. In children with hair loss, it is important to ask the parent and child if the child is pulling out and eating hair. Treatment of this disorder is similar to that for OCD, with the use of selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine) and cognitive-behavioral therapy (Johnson & El-Alfy, 2016; Keuthen et al., 2012). This hair pulling is seen as being on the spectrum of OCD in contrast to other forms of self-mutilation, such as self-cutting seen in teenagers, which fall on the mood and personality disorder spectrums.

Anxiety Disorders

Anxiety disorders include the *DSM-IV-Text Revision* classifications GAD, panic disorder, social anxiety disorder, OCD, and PTSD. In *DSM-5*, skin-picking

disorder has been added (APA, 2013). Anxiety disorders not discussed in this section include separation anxiety, where children become anxious when away from family or the home, and simple phobias such as being frightened of needle sticks or the dark.

Generalized Anxiety Disorder The diagnosis of GAD requires at least 3 months of excessive anxiety and worry most days about two or more of the following: family, health, finances, or school (APA, 2013). The child has difficulty controlling the worry and has accompanying symptoms, including restlessness, quick fatigue, problems concentrating, irritability, muscle tension, and disturbed sleep. The child also shows marked avoidance of, or marked time and effort spent preparing for, situations with potentially negative outcomes. In addition, the child procrastinates in behavior or decision making due to worries and needs repeated reassurances. The child has problems at home or school because of the anxiety, and the anxiety is unrelated to another psychiatric or medical illness. A recent study found that children with an intellectual disability had significantly higher rates of anxiety than typically developing children (Green, Berkovits, & Baker, 2015). Treatment includes cognitive-behavioral therapy to reduce worry (as discussed in Box 27.2) and at times medication such as SSRIs or serotonin-norepinephrine reuptake inhibitors (Creswell, Waite, & Cooper, 2014; Moskowitz et al., 2017; Strawn, Welge, Wehry, Keeshin, & Rynn, 2015). Several studies have shown that medications are effective for pediatric anxiety disorders. Sertraline, duloxetine, and fluvoxamine have been found to be effective in treating GAD in children (Rynn, Siqueland, & Rickels, 2001; Strawn et al., 2015; Walkup et al., 2001). Fluvoxamine is also effective in treating other anxiety disorders, such as social phobia and separation anxiety disorder (Walkup et al., 2001). More recently, a large National Institute of Mental Health (NIMH) study demonstrated that a combination of sertraline and cognitive-behavioral therapy resulted in a better

BOX 27.2 EVIDENCE-BASED PRACTICE

Cognitive-Behavioral Therapy to Treat Childhood Anxiety

Cognitive-behavioral therapy (CBT) is the most widely studied and commonly used treatment for childhood anxiety (Olatunji, Cisler, & Deacon, 2010). However, few studies have examined the effectiveness of CBT for treating anxiety in children with developmental disabilities. Randomized control trials have found CBT to be effective for treating anxiety in children with autism spectrum disorder (Wood et al., 2009), but further research is needed to determine the effectiveness of CBT to treat anxiety in children with other developmental disabilities.

outcome in childhood anxiety disorders than either treatment alone (Walkup et al., 2008).

Panic Disorder To meet diagnostic criteria for panic disorder, an individual must have one or more panic attacks that include at least four of the symptoms listed in Table 27.2. People with panic disorder have panic attacks that recur; are unexpected; and combine with worry about having more panic attacks, worry about the consequence of an attack (e.g., that the child might die or go crazy), or worry leading to a significant change in behavior due to the attacks (e.g., stopping exercise because of a fast heartbeat, rapid breathing, and sweating—feeling like a heart attack). Since panic attack symptoms can mimic other disorders such as heart problems, stomach disorders, seizures, and asthma, appropriate treatment is often delayed while other medical causes are ruled out. In patients with panic disorder, other family members also may have or have had a history of anxiety disorder or panic attacks as there appears to be a genetic component.

Panic attacks do not usually begin until puberty. Adolescents with panic disorder may begin to avoid certain places or situations such as crowds, public transportation, and other places where a panic attack could occur. This maladaptive change in behavior can lead to avoiding exercise or unfamiliar situations or, in extreme cases, to comorbid agoraphobia (fear of leaving the house). Patients with panic disorder can be treated with high-potency benzodiazepines such as alprazolam and clonazepam alone or in combination with SSRIs (Batelaan, Van Balkom, & Stein, 2012). Patients with panic disorder can also be helped through cognitive-behavioral therapy (Hofmann, Asnaani, Vonk, Sawyer, & Fang, 2012; Kircher et al., 2013). In cognitive-behavioral therapy, patients develop a list of things that are least to most likely to cause a panic

attack and then work their way through the list, facing the different issues that cause the attacks. The therapist helps the individual devise strategies to temper or overcome the attacks in real time and observes how the anxiety decreases over time.

Social Anxiety Disorder A phobia particularly relevant to children is social anxiety disorder, which includes school phobia. In this disorder, there is an intense fear (phobia) of acting in a way or showing anxiety symptoms that will be negatively evaluated. The fear is out of proportion to the actual danger posed by the social situation. For children, social anxiety disorder may result in not only making excuses to avoid going to school, but also practicing *selective mutism* in which the child does not speak at all in school but speaks normally in other situations.

Social phobia involves a marked and persistent fear of one or more social or performance situations in which a person is exposed to strangers or to scrutiny by others and worries about possibly doing something embarrassing. A diagnosis for this disorder involves a child having appropriate relationships with family members and friends but being afraid of other peers and adults. Exposure to the social situation (e.g., a birthday party) provokes anxiety and the child may cry, have a tantrum, freeze, or shrink from situations with unfamiliar people. The child may not be aware that the fear is unreasonable, and the fear must impair social functioning. Social phobia is classified as generalized if it takes place in multiple settings, and the symptoms must last for more than 6 months. Treatment includes cognitive-behavioral therapy to reduce anxiety in social situations, speech-making and acting classes for people with performance anxieties, and the use of SSRIs. Children with extreme cases of social phobia are too frightened to speak in the classroom, eat in the cafeteria, or use the restroom at school. This can markedly impair school performance and should not be dismissed as simple shyness. Some children with a variant of social phobia may, like children with social anxiety disorder, have selective mutism, in which they refuse to speak to unfamiliar people or children; SSRIs and behavioral therapy may be helpful in this case (Bergman, Gonzalez, Piacentini, & Keller, 2013; Mohatt, Bennett, & Walkup, 2014). Girls with fragile X syndrome have high rates of both social phobia (55%) and selective mutism (21%; Wadell, Hagerman, & Hessel, 2013).

Table 27.2. Symptoms of panic disorder

Rapid or racing heartbeat
Sweating, trembling, or shaking
Feeling short of breath or as if being smothered
Feeling as if choking
Chest pain or discomfort
Nausea or abdominal distress
Feeling dizzy, lightheaded, or faint
Feeling of unreality or detachment (like floating or in a dream)
Fear of losing control or going crazy
Fear of dying
Numbness and tingling
Hot flashes or chills

Note: At least four symptoms need to be present during an attack for a diagnosis of panic disorder.

Obsessive-Compulsive Disorder A child with OCD has obsessions, compulsions, or both. **Obsessions** are recurrent thoughts, images, or impulses that are experienced as intrusive and inappropriate and cause

anxiety or distress. The obsessions are not excessive worries about real-life problems (as in generalized anxiety), and individuals attempt to ignore, suppress, or neutralize the obsessions. Children may not be aware that the obsessions and compulsions are unreasonable; furthermore, children with a developmental disability may not realize that the obsessions are a product of the mind. **Compulsions** are repetitive behaviors (e.g., hand washing) or mental acts (e.g., praying or counting) that are done to neutralize an obsession or as part of following rigid rules. A child with obsessions about germs would have washing compulsions to neutralize the germs. The compulsions are designed to reduce distress or to prevent some dreaded act. For example, a child might refuse to step on green tiles in the school corridor because the child believes his or her mother might die if the child stepped on green tiles. Children, especially younger ones, are more likely to have compulsions without the accompanying obsessions; thus, a child might have an elaborate 2-hour bedtime ritual without self-awareness regarding why their bedtime ritual is that certain way.

Some children develop the rapid onset of OCD after a streptococcal skin or throat infection. This is referred to as pediatric autoimmune neuropsychiatric disorders associated with *Streptococcus* infections or PANDAS (Chiarello, Spitoni, Hollander, Matucci Cerinic, & Pallanti, 2017). The first report of pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) was published by Swedo and colleagues in 1998. Like adult OCD, PANDAS is associated with basal ganglia dysfunction (Orefici, Cardona, Cox, & Cunningham, 2016). Treatments for PANDAS include treatment of underlying infections with antibiotics, psychotropic medications such as benzodiazepines, and behavioral interventions such as cognitive-behavioral therapy (Thienemann et al., 2017).

Common compulsions in children include ordering and arranging, counting, tapping, touching, and collecting/hoarding. Nearly all children exhibit some or all of such behaviors during development. Therefore, in order to meet criteria for the diagnosis, the obsessions and compulsions must consume more than 1 hour per day and interfere with functioning. The definition also quantifies the level of insight by the child for the irrationality of the OCD as absent, poor, or good insight (APA, 2013). It has been found that poor or absent insight is common among children with OCD, especially in children with intellectual disabilities (Lewin et al., 2010). Individuals with chronic tic disorder may exhibit OCD symptoms, and children with ASD may exhibit OCD-like rigidity and repetitive, compulsive behaviors (see Chapter 18).

Treatment of OCD in children and adolescents includes cognitive-behavioral therapy, which is aimed at experiencing the obsessive thought without carrying out the compulsion designed to reduce the anxiety. This form of therapy is called exposure-and-response prevention. A child with fear of germs would be asked to touch a doorknob and then be forbidden to wash his or her hands. Children have weekly assignments in this therapy. Several medications are also approved for the treatment of OCD in children, including clomipramine, sertraline, fluoxetine, and fluvoxamine (DeVaugh-Geiss et al., 1992; Geller et al., 2001; March et al., 1998; Riddle et al., 2001). One paper in the literature described the difference in outcome among children with OCD who were treated with one of four treatments: sertraline, placebo, cognitive-behavioral therapy, or a combination of medication and therapy (Pediatric OCD Treatment Study Team, 2004). Of the four options, the combination therapy helped the most children, followed by cognitive-behavioral therapy alone, sertraline alone, and then placebo. OCD can be comorbid with other developmental disabilities, especially ADHD and ASD.

Posttraumatic Stress Disorder PTSD is an anxiety disorder that occurs after exposure to a traumatic event in which the person experiences or witnesses an actual or threatened death, serious injury, or (in the case of a child) the loss of a parent or other attachment figure. In children with developmental disabilities, PTSD may occur after physical abuse or after the injury that caused the disability. Children with intellectual disability are particularly at risk for PTSD, as they have more limited coping skills. The child responds to the inciting event with intense fear, helplessness, or horror and may have disorganized or agitated behavior. A child with a diagnosis of PTSD must have symptoms for at least 1 month and have impaired functioning. The symptoms are broken down into three categories: re-experiencing the trauma, avoidance and numbing, and increased arousal. Re-experiencing behavior includes 1) recurrent recollections of the event (in children, this may manifest as a repetitive theme in play), 2) dreams of the event (children may have distressing dreams that are not trauma specific, and children do not necessarily need to be able to remember the content of the dreams), 3) flashbacks of the event (children may reenact the trauma), 4) intense mental distress at physical or mental cues that remind the child of the event, and 5) physiological reactivity on exposure to cues that remind the child of the event. Avoidance behavior includes 1) efforts to avoid thoughts or feelings associated with the trauma, 2) efforts to avoid people and places associated with the trauma, 3) inability to recall important

aspects of the trauma, 4) decreased interest or participation in activities, 5) feelings of detachment or estrangement, 6) a restricted range of feelings, and 7) a sense of a shortened future. Symptoms of increased arousal include 1) difficulty sleeping, 2) irritability or angry outbursts, 3) difficulty concentrating, 4) hypervigilance, and 5) an exaggerated startle response. PTSD is characterized by duration, either acute (3 months or less) or chronic (more than 3 months), and by delayed onset (starts 6 months after the trauma).

Treatment of PTSD has included both psychotherapy and SSRIs, and a recent meta-analysis includes a critical review of the published trials (Morina, Koerssen, & Pollett, 2016). The largest controlled trial of the SSRI sertraline in PTSD failed to show that medication was superior to placebo (Robb, Cueva, Sporn, Yang, & Vanderburg, 2010). Other studies have shown that trauma-focused cognitive-behavioral therapy shows the best efficacy in youth with PTSD (Ehlers et al., 2014). Patients must practice talking through the thoughts and events that remind them of the incident that elicited the PTSD. Play therapy, in which a child has a chance to relive and triumph over the trauma, may also help work through the loss. Therapy must be based on the cognitive level of the child.

Skin Picking (Excoriation) Disorder In this anxiety disorder, skin picking results in actual skin lesions. Skin picking also causes clinically significant distress or impairment in social, occupation, or other important areas of function. Medical afflictions (e.g., scabies) and other psychiatric disorders (e.g., psychosis) must be eliminated from consideration to make this diagnosis.

Mood Disorders

Mood disorders that may impact children include major depression and bipolar disorder.

Major Depression Children carrying a diagnosis of major depression must have a 2-week period with at least five of the following symptoms that represent a change from previous functioning: 1) depressed mood by subjective report or as observed by others (children and adolescents may have an irritable mood), 2) decreased interest or pleasure in most activities, 3) significant change in weight or appetite (children may fail to make expected weight gains), 4) insomnia or hypersomnia (excessive sleep), 5) psychomotor agitation or retardation, 6) fatigue or loss of energy, 7) feelings of worthlessness or guilt, 8) decreased concentration or indecisiveness, and

9) recurrent thoughts of death and dying. Symptoms must not be due to bereavement and must cause impairment in the child's daily function.

A review of depression in trisomy 21 showed that although antidepressants, electroconvulsive therapy, and psychotherapy were all effective, many people with Down syndrome and depression were undertreated (Walker, Dosen, Buitelaar, & Janzing, 2011). In addition, depressive symptoms and social relating problems in children with trisomy 21 have been found to persist into adulthood (Foley et al., 2015).

In a review of 257 clinic patients with fragile X disorder with anxiety, mood disorder, ADHD, and aggression, Berry-Kravis, Sumis, Herve, and Mathur (2012) noted that the patients had success rates that varied by treatment, including a 53% response to antidepressants and 54% response to antipsychotics. Those children with fragile X who failed one medication trial had a 73%–77% of responding to a sequential trial in the same category of medication.

In general, children with major depression can be treated with medication or psychotherapy or a combination of both. Studies have shown that several SSRIs are superior to a placebo in the treatment of depression (Emslie et al., 2002; Wagner et al., 2003; Wagner et al., 2004). An NIMH study found that for adolescents with major depression, placebo and cognitive-behavioral therapy alone were similar in improvement, whereas fluoxetine was better, and fluoxetine plus cognitive-behavioral therapy had the best outcome (Treatment for Adolescents with Depression Study Team, 2004). It also has been shown that treatment with a combination of cognitive-behavioral therapy and fluoxetine results in a significantly lower risk of relapse compared to treatment with fluoxetine only in children with major depression (Kennard et al., 2014).

Bipolar Disorder Bipolar disorder consists of swings between depression and **mania/hypomania**. A manic episode consists of a distinct period of abnormally and persistently elevated, expansive, or irritable mood lasting at least 1 week. The mood disturbance must have three of the following symptoms (four symptoms are necessary if irritable): 1) inflated self-esteem or grandiosity, 2) decreased need for sleep, 3) more talkative or pressured speech or vocalizations (in nonverbal children), 4) flight of ideas (idea moves from topic to topic) or racing thoughts, 5) distractibility, 6) increased goal-directed activity or psychomotor agitation, and 7) excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., promiscuity, drug use, or spending sprees). Hypomania is a less severe set of symptoms than mania. A patient with hypomania would not need

to be hospitalized. They would have symptoms for less than 7 days, would only have two of the manic symptoms, or continue to do well at school and home despite silly, goofy behavior.

Individuals with bipolar disorder are treated with mood stabilizers such as lithium or valproic acid (which is also used as an antiepileptic drug and is not U.S. Food and Drug Administration (FDA) approved for the treatment of bipolar disorder in children or adolescents). The only positive trial of an antiepileptic drug for pediatric bipolar disorder is the add-on trial of lamotrigine in pediatric bipolar disorder manic or depressed episode that was effective in reducing bipolar symptoms in youth over the age of 12 (Findling et al., 2015a). They may also benefit from antipsychotic medication such as risperidone, aripiprazole, olanzapine, quetiapine, and ziprasidone in conjunction with mood stabilizers or as monotherapy (use of antipsychotics alone). All of these medications (except ziprasidone) are FDA approved for the treatment of bipolar disorder with mixed or manic episodes in older children and teenagers. Combination therapy with olanzapine and fluoxetine has also been found to be effective and has been FDA approved for treating bipolar depression in adolescents (Detke, DelBello, Landry, & Usher, 2015). Children with bipolar disorder must have consistent bedtimes and routines to ensure that lack of sleep does not precipitate either a manic or mixed episode.

Psychotic Disorders

Psychotic disorders (sometimes called “psychosis”) consist of alterations in thinking or perceptions that are not connected with reality. The primary psychotic disorder is **schizophrenia**. The diagnosis of schizophrenia requires the presence of one or more of the following three symptoms for at least 6 months, with active symptoms for 1 month or less if treated: 1) **delusions** (fixed idiosyncratic false belief; e.g., that someone is following the person), 2) **hallucinations**

(sensory perception without an environmental stimulus; e.g., hearing a voice when no one else is present), and 3) disorganized speech (APA, 2013). In children, there will be an associated failure to achieve expected levels of interpersonal relationships and academic achievement.

Patients with a mood disorder or an ASD may have psychotic symptoms that are confused with the formal diagnosis of schizophrenia, as examined in Box 27.3. An individual with ASD must have prominent delusions or hallucinations to meet the schizophrenia diagnosis in addition to ASD. Other medical conditions that can mimic schizophrenia include epilepsy, effects of an illegal drug, and brain tumors. Once the diagnosis of schizophrenia has been confirmed, treatment with antipsychotic drugs will reduce the delusions and hallucinations, thereby improving psychosocial functioning. Six atypical antipsychotic medications for schizophrenia are approved for adolescents 13 years and older: aripiprazole, olanzapine (a second-line drug due to metabolic adverse effects), quetiapine, paliperidone, risperidone, and lurasidone (Findling et al., 2008; Findling et al., 2012; Goldman, Loebel, Cucchiaro, Deng, & Findling, 2017; Haas et al., 2009; Kryzhanovskaya et al., 2009; Singh, Robb, Vijapurkar, Nuamah, & Hough, 2013). Trials of ziprasidone and asenapine for adolescent schizophrenia have failed to show a benefit compared with placebo (Findling et al., 2013; Findling et al., 2015b).

Eating Disorders

The three important types of eating disorders that occur in children with developmental disabilities are rumination, binge eating, and pica. In **rumination**, infants or young children repeatedly regurgitate without nausea or gastrointestinal illness for at least 1 month. Regurgitated food may be rechewed, reswallowed, or spit out. To meet the definition of rumination in the context of intellectual disability or ASD, regurgitation should be sufficiently frequent and severe to warrant

BOX 27.3 EVIDENCE-BASED PRACTICE

Autism Spectrum Disorder and Psychotic Disorders

Autism spectrum disorder (ASD) and psychotic disorders such as schizophrenia have historically been considered related disorders (Kyriakopoulos et al., 2015). The disorders share phenotypic characteristics and neurobiological structural similarities (Cheung et al., 2010). However, the two disorders remain clinically distinct. Therefore, although ASD and schizophrenia may share common etiologies, it is important to understand how these disorders are distinct for effective treatment.

independent clinical attention because it may instead be a self-stimulatory behavior in these children. Treatment includes behavioral interventions and the use of gastrointestinal motility agents (e.g., laxatives; Luiselli, 2015; Woods, Luiselli, & Tomassone, 2013). One study of 55 adolescents with rumination found that patients with a comorbid mental health disorder were less likely to respond to treatment (Alioto, Yacob, Yardley, & Di Lorenzo, 2015).

The second common eating disorder is **binge eating**, whereby the child has recurrent episodes of eating large amounts of food during short periods of time. Binge-eating episodes demonstrate at least three of the following features: 1) eating much more rapidly than normal; 2) eating until feeling uncomfortably full; 3) eating large amounts of food when not feeling physically hungry; 4) eating alone because of embarrassment over how much one is eating; and 5) feeling disgusted with oneself, depressed, or very guilty afterwards. The binge-eating episodes should not occur exclusively during the course of anorexia, bulimia, or avoidant/restrictive food intake, and they must occur on average at least once a week for 3 months (APA, 2013). It should be emphasized that children who do binge risk choking to death. Binge eating is a frequent complication of and contributes to the morbid obesity seen among individuals with Prader-Willi syndrome. Children with a binge-eating disorder need nutritional guidance and counseling, parental and school oversight of meals, limited access to food outside of meals, and an exercise routine. For some children with a severe binge-eating disorder, admission to a long-stay residential setting with strict oversight of meals and activity levels can dramatically change the child's weight and improve the underlying medical condition. Untreated ADHD, especially in girls, has been found to place them at higher risk for binge eating in adolescence and young adulthood (Biederman, 2010).

Pica, the persistent craving and ingesting of non-food items, is a typical behavior of toddlers. When a child older than 2 years displays pica, however, professionals should explore the possibility that the child has a psychiatric disorder or a nutritional deficiency. Also, pica in older children can also be a typical behavior of individuals with severe to profound intellectual disability. Pica from any cause described above can seriously affect a child's well-being. It can result in toxicity from ingested materials such as medications or lead-containing plaster or paint chips, and it can physically damage the gastrointestinal tract. Behavior management techniques (see Chapter 34) have been found to be the most effective intervention for pica (Williams & McAdam, 2012).

Adjustment Disorders

These disorders involve the development of emotional or behavioral symptoms in response to an identifiable stressor and occur within 3 months of the onset of that stressor. The symptoms or behaviors are clinically significant and cause marked distress, in excess of what would be expected from exposure to the stressor, and are accompanied by significantly impaired social or occupational (academic) functioning. With the exception of an ASD, individuals with adjustment disorders do not have another major psychiatric disorder. Once the stressor ends, the symptoms do not persist for more than 6 months. Adjustment disorder with anxiety has symptoms such as nervousness, worry, or jitteriness or, in children, separation anxiety focused on parents. Adjustment disorder with depressed mood includes depression, tearfulness, or hopelessness as the predominant symptoms. Adjustment disorder with disturbances of conduct presents with significant problematic behaviors such as truancy, vandalism, reckless driving, or fighting. Finally, adjustment disorder with mixed disturbance of emotions and conduct includes anxiety or depression plus conduct symptoms.

Children with developmental disabilities may be at higher risk for adjustment disorders because they have limited coping skills and frequently have medical illnesses or require procedures that produce stress. When children with developmental disabilities enter the hospital for a medical procedure or illness, parents, caregivers, and health care providers must be prepared for exaggerated emotional and behavioral responses to being in the hospital and kept away from their normal routine. Children may cry, have tantrums, or act out, or they may alternatively become quiet and withdrawn, refusing to eat or cooperate with staff. Patience and reassurance will generally help the child navigate the stressful situation and return to his or her baseline emotional and behavioral functioning. Interventions to help prevent and treat these adjustment disorders include allowing parents to stay overnight in the hospital and allowing the child to bring special bedding, pillows, transitional objects (e.g., security blankets), stuffed animals, or favorite books or games to improve the child's comfort in the hospital. Visits to the hospital or treatment center ahead of an admission may also help provide familiarity with new places and people and thus diminish fear. One study found that picture schedules can help to relieve anxiety in children with ASD (Chebuhar, McCarthy, Bosch, & Baker, 2013). Such techniques have been found useful in treating children with intellectual disabilities by facilitating better communication with patients and their families, which reduces stress associated with hospital stays (Oulton, Sell, Kerry, & Gibson, 2015).

Maladaptive Behavior Disorders

Some individuals with severe to profound levels of intellectual disability develop behavioral symptoms that are qualitatively different from those seen in people without developmental disabilities. For instance, studies have shown a higher incidence of aggression and SIB in children with developmental disabilities (Schroeder et al., 2014) and that these behaviors are often persistent (Sandman, Kemp, Mabini, Pincus, & Magnusson, 2012). These symptoms, which include repetitive self-stimulating behavior and SIB, can vary among different genetic syndromes (Arron, Oliver, Moss, Berg, & Burbidge, 2011). It is important to identify these behaviors early in childhood for effective intervention.

Individuals who engage in SIB typically display a specific pattern for producing injury. They may bang their heads, bite their hands, pick at their skin, hit themselves with their fists, or poke their eyes. They may do this once or twice a day in association with tantrums, or as often as several hundred times an hour. Tissue destruction, infection, internal injury, loss of vision, and even death may result. These behaviors may be accompanied by additional repetitive, stereotyped behaviors, such as hand waving and body rocking. When these repetitive behaviors interfere with activities of daily living or result in significant injury to the individual, a diagnosis of *stereotypic movement disorder* with SIB is made.

Although serious SIB occurs in fewer than 5% of people of all ages with intellectual disability, these behaviors cause enormous distress to the individuals and their caregivers. Serious SIB can result in severe bodily injury and may lead to residential placement, separating the individual from the family and other community contacts. Some children with SIB also demonstrate severe aggressive behavior toward their caregivers or peers.

SIB is a puzzling and disturbing phenomenon that prompts asking why these individuals hurt themselves. Although no simple answer exists, there is evidence for both environmental and biological causes in the context of enormous individual variation (Schroeder et al., 2014). Some children exhibit SIB because it elicits a desired environmental outcome (i.e., **operant control**; Loschen & Osman, 1992). For example, a girl who is nonverbal but demonstrates head banging will have that reinforced once she learns that this action captures the attention she craves. Other environmental factors that can reinforce SIB include access to desired items (e.g., food), avoidance of task demands (e.g., chores), and certain sensory effects

(e.g., bright lights from eye pressing; Mace & Mauk, 1995). The inference that the sensations produced through self-induced painful stimulation may somehow be gratifying has led to the notion that SIB plays a role in regulating physiologic states such as arousal. Guess and Carr (1991) proposed a biobehavioral model in which the regulation of normal sleep, wake, and arousal patterns is delayed or disturbed in some individuals. These individuals then develop stereotypic movements and SIB as a way to self-regulate arousal in understimulating or overstimulating environments. There is also a relationship between SIB and pain in nonverbal children with severe cognitive impairment. They have been found to increase SIB during an ear infection, constipation, or other conditions associated with pain (Peebles & Price, 2012). Other biological factors are suggested by the increased prevalence of SIB in certain genetic syndromes, including fragile X, de Lange, Lesch-Nyhan, Prader-Willi, and Rett syndromes (see Appendix B; Bailey et al., 2012). Psychiatric disorders such as ASD, depression, mania, and schizophrenia are also risk factors for SIB. General medical conditions and medication side effects can be acute precipitants of SIB. For example, a painful middle-ear infection may lead to head banging. Repetitive or ritualistic behavior also has been found to be associated with increased risk for SIB (Davies & Oliver, 2016; Oliver, Petty, Ruddick, & Bacarese-Hamilton, 2012; Petty, Bacarese-Hamilton, Davies, & Oliver, 2014). Evaluating any individual for the cause of SIB includes examining the roles of reactivity to pain and sensory inputs (Summers et al., 2017).

Although the brain mechanisms underlying most forms of SIB remain unknown, several neurotransmitters are thought to be involved. These include dopamine, which mediates certain reinforcement systems in the brain; serotonin, the depletion of which is sometimes associated with violent behavior; gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter; and opioids, the brain's natural painkillers (Verhoeven et al., 1999). The atypical antipsychotic risperidone has been found to be useful in treating SIB (Zarcone et al., 2001) together with applied behavior analysis. As of 2006, risperidone was FDA approved for the treatment of violent and aggressive behavior, including SIB in individuals with ASD. Also, by 2009 aripiprazole was approved for treating irritability and aggression in children and adolescents with ASD (Robb et al., 2010). Behavioral interventions may also be helpful in treating SIB in children with intellectual disabilities, with early intervention being most effective (Kurtz, Chin, Robinson, O'Connor, & Hagopian, 2015; Schroeder et al., 2014).

VULNERABILITY

Individuals with developmental disabilities are at higher risk for psychiatric disorders than their typically developing peers for a variety of reasons, including 1) higher rates of certain psychiatric disorders in specific syndromes (e.g., ADHD in Williams syndrome or irritability in ASD), 2) impairment in the acquisition of age-dependent coping skills (e.g., some syndromes particularly affect skill development including trisomy 21 and fragile X syndrome), 3) multiple hospital stays for treatment of associated medical problems (e.g., surgical releases of contractures in cerebral palsy), 4) physical differences readily seen by peers who may bully the child (e.g., facial features in trisomy 21, skin lesions in neurofibromatosis, and morbid obesity in Prader-Willi syndrome), and 5) a family history of psychiatric disorders that adds to the genetic risk for mental illness in the child with developmental disability. Children with intellectual disabilities also are more likely to experience victimization and chronic loneliness, which increases their risk for a range of mental health problems (Berg, Shiu, Msall, & Acharya, 2015; Gilmore & Cuskelly, 2014). When assessing patients with developmental disabilities for psychiatric symptoms, the practitioner must also consider changes in school, classmates, and living situations, including family members and pets. These socio-environmental factors can either increase or decrease the risk for mental health problems.

EVALUATION

Psychiatric needs can be met only if parents, teachers, and other staff who work with children with disabilities are aware that emotional disturbances may be present. Ideally, the referral for evaluation should be made to professionals (e.g., psychiatrists, psychologists, behavioral neurologists, developmental-behavioral pediatricians, neurodevelopmental pediatricians, and social workers) with specific training, experience, and expertise in the psychiatric disorders of children with developmental disabilities. The goal of evaluation is to formulate an intervention plan based not only on the psychiatric diagnosis, but also on the developmental level of the child, accompanying medical conditions, the family's strengths and challenges, and the needs and limitations of the settings where the child spends his or her time. Often this requires referral to a specialized tertiary care center with a multidisciplinary team, such as a university hospital. Less experienced mental health professionals who undertake such evaluations should have access to consultation from a specialized center.

The mental health professional first takes a detailed history of the current symptoms and problematic behaviors from parents or other caregivers. For example, recent changes in sleep pattern, appetite, or mood provide important evidence of depression. In addition, an individual and family medical history should be obtained. The family history may reveal, for example, other members with mood or anxiety disorders. A review of the individual's past medical and psychological assessments may indicate prior behavior or psychiatric problems. After taking the history, an interview is conducted posing both structured and open-ended questions to the child and parents. If impairments in communication and cognitive skills are significant, the professional can still gain important information from directly observing the child both alone and with parents (King, DeAntonio, McCracken, Forness, & Ackerland, 1994). Input from the school and other care providers frequently helps clarify the diagnostic issues.

The evaluation should also focus on the social system and setting in which the psychiatric disorder occurs. Thus, the professional should evaluate the current level of family functioning by assessing 1) family members' ability to cope with the child's psychiatric disorder and therapy; 2) their current morale, problem-solving abilities, external social supports, and practical resources (e.g., finances and insurance); 3) the system of beliefs that sustains their efforts; and 4) the stability of the parents' relationship. It is important to understand how individual family members are reacting and adjusting to the child's underlying developmental disability as well as any current mental health problems (see Chapter 37). For example, studies have found that parenting stress can result from and be a cause of child behavior problems and is a risk factor for psychiatric disorders in children with intellectual disabilities (Gallagher & Whiteley, 2013; Neece, Green, & Baker, 2012; Valicenti-McDermott et al., 2015).

Following the comprehensive interview, the child may be referred for psychological testing or behavioral assessment. Although standardized behavior rating scales are available, they are insufficient by themselves as diagnostic tools. A single, structured psychological testing instrument may not be able to cover the range of developmental levels and behavioral baselines exhibited by individuals with developmental disabilities. These instruments are important, however, for confirming or adding to information obtained from the history and interview. They can also be extremely helpful in measuring changes that occur during the course of intervention (Aman, Burrow, & Wolford, 1995; Demb, Brier, Huron, & Tomor, 1994; Linaker & Helle, 1994; Reiss & Valenti-Hein, 1994).

Standardized rating scales may be combined with a functional behavior analysis. This type of combined assessment is most useful regarding children with severe behavioral abnormalities for which specific family or behavior therapies are being considered. One of the more helpful rating scales, the Aberrant Behavior Checklist, can be completed by parents or caregivers; is normed on the developmentally disabled population; and tracks five subscales, including irritability and hyperactivity (Aman et al., 1995; see Box 27.4). This scale can be given at baseline and then tracked over time to evaluate responses to interventions both pharmacologic and behavioral. However, as discussed in Box 27.4, it is important to combine such scales with other evaluations such as behavior analysis. Behavior analysis provides direct observation of the child in a natural setting, yielding a clear description of the abnormal behavior itself and its antecedents and consequences (see Chapter 34). Often, changes in a child's environment such as a new teacher, classmate, or bus driver or other changes in a child's routine can precipitate behavioral symptoms.

It is important to note that many symptoms of a psychiatric disorder can actually be caused by a variety of medical disorders and treatments. For example, hypothyroidism, which is common in individuals with Down syndrome, can cause emotional disturbances that present as anxiety or depression. In excessive (and sometimes therapeutic) dosages, drugs used to treat associated impairments such as epilepsy can cause symptoms of hyperactivity or depression (Stephen, Wishart, & Brodie, 2017). Careful evaluation for medical conditions or drug reactions should be a part of any assessment of new-onset behavioral or psychiatric symptoms.

After the evaluations have been completed, the professional can start formulating an intervention plan based on the psychiatric diagnosis, the child's developmental level, accompanying medical conditions, the family's strengths and challenges, and the needs and

limitations of the settings where the child spends his or her time.

TREATMENT

Treatment of psychiatric illness in children and adolescents with developmental disabilities involves some or all of the modalities described in the following sections. Interventions must be tailored to each child's needs at home, at school, and with peers. The treatment modalities utilized may need to be adjusted as the child matures and individual needs change.

Educational Interventions

Educational interventions can include a variety of supports to help a child succeed in the classroom (see Chapter 33). Children may benefit from schoolwide positive-behavior interventions and supports, with an individualized behavior intervention plan being developed if necessary. The education setting can also be a form of support. Children may be placed in smaller self-contained classes or included in the general education class but with extra aides or a one-to-one helper. When the child becomes upset, the aide can help calm the child, avoiding the need to leave the classroom. The child may also benefit from therapy sessions with the school counselor or behavioral psychologist. There should be close collaboration among school personnel, parents, and the child's medical team, as discussed in Box 27.5.

Rehabilitation Therapy

There is evidence that language impairments significantly contribute to the development of certain behavior problems. Some aggressive behaviors and SIBs have been linked to the inability to communicate needs, and teaching functional communication skills has been shown to decrease SIB. In children with trisomy 21,

BOX 27.4 EVIDENCE-BASED PRACTICE

The Aberrant Behavior Checklist

The Aberrant Behavior Checklist (ABC; Aman et al., 1995) is used to identify maladaptive behaviors in children with developmental disabilities. However, recent research on the use of this scale as an outcome measure for clinical trials on fragile X syndrome has found that the ABC subscales may not be sensitive to symptoms of patients with higher-functioning fragile X syndrome (Sansone et al., 2012). Such research should be taken into consideration when using this scale as an outcome measure for children with intellectual disabilities, as it highlights the importance of using rating scales in combination with comprehensive interviews.

BOX 27.5 EVIDENCE-BASED PRACTICE**Children with Intellectual Disabilities in School**

McIntyre, Blacher, and Baker (2006) found that children with an intellectual disability showed poor adaptation to school compared with typically developing children and that this led to more maladaptive behavior and decreased social skills, which are both risk factors for psychiatric disorders. These findings highlight the importance of early intervention in educational settings and collaboration with school staff and caregivers of children with intellectual disability.

increased disruptive behaviors often indicate underlying medical concerns or frustration that results from the patient's inability to communicate (Skotko, Davidson, & Weintraub, 2013). Children with fragile X syndrome, ASD, and trisomy 21 are significantly less likely than their typically developing peers to signal noncomprehension in communication, which could lead to further challenges in language and academic development (Martin et al., 2017). Thus, speech-language therapy and training in augmentative and alternative communication systems (see Chapters 17 and 36) may be an important part of the intervention program. Similarly, if the child has a physical disability, pain from contractures, an inability to ambulate, or difficulty reaching for desired objects may lead to behavior and mood alterations. Physical and occupational therapy may improve motor function, with associated improvement in behavior and mood.

Psychotherapy

There is ample evidence that various forms of psychological or behavioral therapy (individual, group, and family) can benefit a child or adolescent with

developmental disabilities and psychiatric disorders, if it is adapted to the child's developmental age and communication abilities (Brosnan, 2011; Kok, van der Waa, Klip, & Staal, 2016; McGinnes, 2010; Plant, 2007). Table 27.3 shows different types of psychotherapy and the disorders that they are most useful in treating. The goals of therapy are to relieve symptoms and help the child understand the nature of the disability and associated feelings and to come to recognize and appreciate his or her strengths. Psychotherapy, particularly group work, can also enhance social skills and help the child deal with stigmatization, rejection, peer pressure, and attempts at exploitation (Kasari, Rotheram-Fuller, Locke, & Gulsrud, 2012; Koning, Magill-Evans, Volden, & Dick, 2013; Reichow, Steiner, & Volkmar, 2013; Walton & Ingersol, 2013; White et al., 2013). Regrettably, individuals with developmental disabilities are seriously underserved regarding psychotherapy despite the fact that psychotherapy can provide a supportive relationship, help restore self-esteem, and enhance the child's capacity to recognize and master emotional conflicts and solve problems (Dykens, 2016). Psychotherapy also can be added to behavior therapy and pharmacotherapy when these approaches have not adequately

Table 27.3. Types of psychotherapy and uses in different disorders

Therapy	Behavior	CBT	Social skills	Group	Individual	Supportive/educational	Parent training
ADHD	X		X	X			X
ODD and conduct disorder	X		X	X			X
Generalized anxiety disorder		X			X	X	
Social phobia		X	X	X	X	X	X
Panic disorder		X			X	X	
PTSD		X			X	X	
OCD		X			X		
Major depression		X			X	X	
Bipolar disorder					X	X	X
ASD	X	X	X	X		X	X
Schizophrenia		X	X		X	X	X

Key: CBT, cognitive-behavioral therapy; ADHD, attention-deficit/hyperactivity disorder; ODD, oppositional defiant disorder; PTSD, posttraumatic stress disorder; OCD, obsessive-compulsive disorder; ASD, autism spectrum disorder.

resolved symptoms or improved quality of life. Ideally, the therapist should have expertise in working with individuals with developmental disabilities.

Behavior therapy is perhaps the most widely researched psychotherapeutic intervention for children and adolescents with intellectual disabilities (see Chapter 34). Cognitive-behavioral therapy and family interventions have been successful in children with ASD. There are extensive findings supporting the effectiveness of behavioral approaches in psychiatric disorders (Benjamin et al., 2011; Weisz, Hawley, & Doss, 2004). When used in conjunction with comprehensive assessment, accurate medical and psychiatric diagnoses, and programmatic intervention, behavior therapy is among the most powerful available interventions. As with other forms of psychotherapy and pharmacotherapy, however, it should be implemented only under the supervision of licensed professionals who have been specifically trained in this methodology.

Pharmacotherapy

Medication can play an important role in treating the psychiatric disorders that occur in children with developmental disabilities (Efron et al., 2003). Box 27.6 discusses ongoing research on evidence-based pharmacotherapy for children with intellectual disabilities, and Table 27.4 lists the various medications in each of the diagnostic groups that are described next. (Additional information on uses and side effects of these medications can be found in Appendix C.) It has long been understood that pharmacotherapy is different in children than in adults. Because human growth and development vary among individuals, there is no single method to determining the appropriate dose of medications. Predictions of drug clearance in children based on weight and metabolic rate have been found ineffective (Mahmood, 2006). Therefore, it is important to take individual differences into account and to begin treatment at a low dose when prescribing psychotropic

medication to children. This is especially important in children with developmental disabilities as these children are at a greater risk for side effects than typically developing children (Ji & Findling, 2016; Simonoff et al., 2013). Medical providers should begin treatment at a low dose and then slowly titrate the dose up.

An example of this was seen in the aripiprazole pediatric trials. Here the titration was quickest in typically developing adolescents with schizophrenia who could accept increased doses every 2 days to a maximum of 30 mg in less than 2 weeks (Findling et al., 2008). In contrast, for children with irritability associated with ASD, when the dose was increased weekly to a maximum dose of 15 mg over 4 weeks, these children had higher rates of side effects despite a lower maximum dose and more gradual titration schedule than their typically developing peers (Robb et al., 2011). In another study, stimulants given to children with ASD were associated with a higher rate of emotional lability, crying, and other side effects than were seen in typically developing preschool children with ADHD (Nickels et al., 2008).

Antidepressants Antidepressants are used to treat major depression and anxiety disorders including OCD, GAD, and separation anxiety disorder (DeVaugh-Geiss et al., 1992; Emslie et al., 2002; Geller et al., 2001; March et al., 1998; Riddle et al., 2001; Wagner et al., 2003; Wagner et al., 2004). Box 27.7 reviews the current FDA-approved antidepressants. The class of antidepressants most commonly used in children and adolescents is the SSRIs.

In 2004, the FDA required drug companies to start putting “black box” warnings—the FDA’s highest level of warning before removing a drug from the market—on the packaging of all categories of antidepressants, as well as atomoxetine for ADHD, aripiprazole for treatment-resistant depression, and quetiapine for bipolar depression, noting the potential risk of suicidality while taking these medications. This requirement

BOX 27.6 EVIDENCE-BASED PRACTICE

Evidence-Based Pharmacotherapy for Children with Intellectual Disabilities

There is limited research on evidence-based pharmacotherapy for children with intellectual disabilities. According to a review by Ji and Findling (2016), antipsychotics such as risperidone seem to be effective in reducing challenging behaviors such as aggression and SIB. Methylphenidate and α -agonists may be effective in treating ADHD symptoms in children with intellectual disabilities. However, antidepressants appear to be poorly tolerated in this population (Ji & Findling, 2016). This information is important to consider when deciding on the best course of treatment for children with intellectual disabilities.

Table 27.4. Medications used to treat psychiatric disorders

	Generic name	Trade name	Type	Uses	Other formulations
Antidepressants	Fluoxetine	Prozac, Sarefem	SSRI	Depression, anxiety, OCD	Liquid and weekly
	Fluvoxamine	Luvox, LuvoxCR	SSRI	OCD	None
	Sertraline	Zoloft	SSRI	Depression, anxiety, OCD	Liquid
	Paroxetine	Paxil, Paxil CR	SSRI	Depression, anxiety, OCD	Liquid (not in CR)
	Citalopram	Celexa	SSRI	Depression	Liquid
	Escitalopram	Lexapro	SSRI	Depression, anxiety	Liquid
	Venlafaxine	Effexor, Effexor XR	SNRI	Depression, anxiety	None
	Duloxetine	Cymbalta	SNRI	Depression, GAD	None
	Bupropion	Wellbutrin, Wellbutrin SR, Wellbutrin XL	Dopaminergic	Depression, ADHD	None
Antihypertensives	Propranolol	Inderal, Inderal LA	Beta blocker	Aggressive behavior	None
	Clonidine	Catapres, Cat-apres-TTS patch	Alpha-2-adrenergic agonist	ADHD, tics, sleeping agent	Weekly skin patch
		Kapvay		Monotherapy or with stimulant	
	Guanfacine	Tenex	Alpha-2-adrenergic agonist	ADHD, tics	None
Antipsychotics		Intuniv		Monotherapy or with stimulant	
	Clozapine	Clozaril	Atypical	Treatment-resistant schizophrenia, bipolar disorder (not FDA approved for acute bipolar mania)	None
	Risperidone	Risperdal, Risperdal M-Tab, Risperdal Consta	Atypical	Schizophrenia, bipolar disorder, aggressive behavior in children with autism spectrum disorder	Liquid, oral dissolving tablets (M-Tab), 2-week injection (Consta)
	Olanzapine	Zyprexa, Zyprexa Zydis, Zyprexa Relprev	Atypical	Schizophrenia, bipolar disorder, acute agitation	Oral dissolving tablets, 2-week injection (Relprev) requires extensive monitoring
	Ziprasidone	Geodon	Atypical	Schizophrenia, bipolar disorder, acute agitation	Daily injection
	Quetiapine	Seroquel	Atypical	Schizophrenia, bipolar disorder (acute mania and bipolar depression)	None
	Aripiprazole	Abilify, Abilify Discmelt	Atypical (plus serotonin agonist)	Schizophrenia, bipolar disorder	Liquid, oral dissolving tablets, daily injection
	Paliperidone	Invega, Invega Sustenna	Atypical	Schizophrenia	4-week injection (Sustenna)
	Asenapine	Saphris	Atypical	Bipolar mixed/manic	Sublingual only
	Lurasidone	Latuda	Atypical	Schizophrenia (bipolar depression pending)	None
	Haloperidol	Haldol, Haldol Decanoate	Typical	Schizophrenia, Tourette syndrome, agitation, severe behavior disorders	Liquid, daily injection, monthly injection
	Pimozide	Orap	Typical	Tourette syndrome	None

(continued)

Table 27.4. (continued)

	Generic name	Trade name	Type	Uses	Other formulations
Benzodiazepines	Lorazepam	Ativan	Typical	Anxiety	Liquid, daily injection
	Alprazolam	Xanax, Xanax XR	High potency	Panic, anxiety	None
	Clonazepam	Klonopin, Klonopin Wafers	High potency	Panic, anxiety	Oral dissolving tablets
Mood stabilizers	Lithium carbonate	Lithobid, Eskalith, Eskalith-CR	Mood stabilizer	Bipolar disorder (acute mania and maintenance)	Liquid
	Valproic acid	Depakote, Depakote ER, Depacon, Depakene	Antiepileptic drug	Bipolar disorder	Liquid, intravenous, sprinkles
	Carbamazepine	Tegretol, Tegretol XR, Carbatrol, Equetrol	Antiepileptic drug	Bipolar disorder	Chewable tablet, liquid
	Oxcarbazepine	Trileptal	Antiepileptic drug	Not FDA approved yet for bipolar disorder, but used	Liquid
Stimulants and atomoxetine	Lamotrigine	Lamictal	Antiepileptic drug	Bipolar maintenance	Chewable tablets
	Methylphenidate–racemic mixture	Ritalin, Ritalin LA, Metadate CD, Concerta, Daytrana	Synthetic stimulant	ADHD	Sprinkles for Ritalin LA and Metadate CD, transdermal patch (Daytrana)
	Dexmethylphenidate	Focalin, Focalin XR	Synthetic stimulant	ADHD	Sprinkles for XR
	Dextroamphetamine	Dexedrine, Dexedrine ER spansules	Stimulant	ADHD	Chewable generic tablet, ER spansule
	Mixed amphetamine salts	Adderall, Adderall XR	Stimulant	ADHD	Sprinkles for XR
	Modafanil	Provigil, Sparlon	Unknown	ADHD (not FDA approved for ADHD due to concern about Stevens-Johnson syndrome)	None
	Atomoxetine	Strattera	NRI	ADHD, maintenance 6–14 years	None

Key: SSRI, selective serotonin reuptake inhibitor; OCD, obsessive-compulsive disorder; CR, controlled release; SNRI, serotonin norepinephrine reuptake inhibitor; XR, extended release; SR, slow release; XL, extra long; ADHD, attention-deficit/hyperactivity disorder; LA, long acting; TTS, transdermal system; ER, extended release; FDA, Food and Drug Administration; CD, controlled delivery; NRI, norepinephrine reuptake inhibitor. For further information see Appendix C.

BOX 27.7 EVIDENCE-BASED PRACTICE**FDA-Approved Antidepressants for Children**

In the 1990s, it became apparent that there were limited data on the use of antidepressants in children that had only been approved by the FDA for adults. In response, the FDA required pharmaceutical companies to provide data on new and existing antidepressants for children (Cheung, Emslie, & Mayes, 2005). Since then, several antidepressants, including fluoxetine (Emslie et al., 2002), sertraline (March et al., 1998), clomipramine (DeVaugh-Geiss et al., 1992), fluvoxamine (Walkup et al., 2001), escitalopram (Wagner et al., 2006), and duloxetine (Emslie et al., 2014) have been FDA approved and found effective to treat disorders such as major depression and anxiety disorders.

resulted in a decrease in SSRI prescriptions and an increase in suicide rates in children and adolescents (Gibbons et al., 2007). Although oversight by regulatory bodies is important to ensure patient safety, this study shows how warnings made by these regulatory bodies may have unintended and potentially harmful effects. More recently the antidepressant black box warning has been revised and expanded to include all those individuals younger than 25 years. The current warning states that these antidepressants may increase suicidal thoughts and actions when first started.

Depression and other mental illnesses are the most important causes of suicidal thoughts and actions, and some people may be at a particularly high risk. Families should watch closely for changes in mood, behavior, and the appearance of suicidal thoughts and actions when starting a child on antidepressants, and clinicians should monitor their young patients for any change in mental state and for indications of suicidal ideas or plans. With these controls in place, antidepressants can continue to be useful in the treatment of pediatric mood and anxiety disorders and remain an important part of treatment for these illnesses (Gibbons et al., 2015; Linden et al., 2016).

In a large study of youth with fragile X syndrome and targeted medication use, the authors tracked target symptoms, medication choice, and age of the patient. Anxiety was the most common symptom being treated in 42% of males and 26% of females. By age 20, 45% of males and 32% of females were taking medication for anxiety (Bailey, Raspa, Bishop, Mallya, & Berry-Kravis, 2012). In a 6-month study of young children ages 2–6 years with fragile X syndrome who were treated with low-dose sertraline (2.5 to 5.0 mg daily) or placebo, they found no difference in the primary outcome on the Mullen Scales of Early Learning for expressive language or clinical global improvement (Hess et al., 2016). However, another 6-month study found that children

ages 2–3 years with fragile X syndrome who were treated with low-dose sertraline (2.5 to 5.0 mg daily) showed more improvement in receptive language compared with children who received a placebo (Yoo, Burris, Gaul, Hagerman, & Rivera, 2017). In another recent study of individuals with 22q11.2 syndrome, both antidepressants and antipsychotics were found to be effective in reducing symptoms of depression anxiety or psychotic symptoms (Dori, Green, Weizman, & Gothelf, 2017).

Antihypertensives Beta-blockers such as propranolol are used to treat explosive and aggressive behavior, whereas alpha-2 adrenergic receptor agonists (e.g., clonidine, guanfacine) are used to treat ADHD, tic disorder, and Tourette syndrome. These medications sedate and can also lower blood pressure; thus, they should be used cautiously, especially in children with developmental disabilities associated with comorbid cardiac disorders (Ahmed & Takeshita, 1996). In the past decade, long-acting formulations of these drugs have been approved by the FDA for the treatment of ADHD in children and adolescents as monotherapy and in combination with stimulant medication (Connor et al., 2010; Jain et al., 2011; Kolins et al., 2011).

Antipsychotic Medications Antipsychotic medications have been used in children and adults since the 1950s to treat disorders, such as schizophrenia and bipolar. More recently, antipsychotic medications have been used to treat aggression and SIB in children with intellectual disability or ASD. There is, in fact, more safety data on risperidone in children with intellectual disability and ASD than in their typically developing peers. In 2006, risperidone became the first antipsychotic medication approved by the FDA for the treatment of

aggressive behavior in individuals with ASD. Aripiprazole has also been approved for the treatment of irritability and aggression in children 6–17 years showing such symptoms in ASD (Robb, 2010). Although these medications have been found to be generally safe and well tolerated in children (Robb et al., 2011), use of antipsychotics to treat disorders in children remains controversial as it has been suggested that children may be at greater risk for adverse events (Vitiello et al., 2009).

Many of the other novel neuroleptics have also been studied in individuals with ASD. Although novel neuroleptics are much more likely to cause weight gain, metabolic syndrome, and diabetes, they are less likely to cause a movement disorder (Scahill et al., 2016; Wink et al., 2014). Another recent study found that antipsychotic medication may have a reparative effect on the white matter microstructure in individuals with 22q11.2 deletion syndrome (Kates et al., 2015).

Benzodiazepines Benzodiazepines are helpful in reducing anxiety in the short term. However, children with developmental disabilities may have paradoxical reactions to these medications—they may become agitated rather than calm and sleepy (Mancuso, Tanzi, & Gabay, 2004; Rothschild, Shindul-Rothschild, Murray, & Brewster, 2000). Although relatively uncommon, the exact mechanisms and cause of paradoxical reactions remain unclear and children appear to be at increased risk (Mancuso et al., 2004). Because chronic use of these agents can cause chemical and behavioral dependency and may alter seizure control, benzodiazepines should not be used for long-term control of anxiety symptoms.

Mood Stabilizers Mood stabilizers include lithium and antiepileptic medication (Findling et al., 2005). They are most commonly used to treat bipolar disorder and aggressive behaviors (see Box 27.8). Lithium is effective in treating current episodes and

in preventing future bipolar episodes (Findling et al., 2015a). It is a salt that is excreted through the kidneys and causes increased thirst and urination. It must be used with caution in combination with certain other drugs that can lead to toxic lithium levels, including nonsteroidal anti-inflammatory drugs (e.g., ibuprofen) and certain anticonvulsants (e.g., topiramate) that are excreted by the kidneys. Lithium toxicity can occur with rapid onset if normal fluid intake is decreased, for example with vomiting, diarrhea, or acute illness; this in turn can result in coma, kidney failure, or the need for dialysis. A recent examination of lithium in mouse and fruit fly models of fragile X syndrome showed reversal of behavioral, physiological, cellular, and molecular phenotypes. This success in the animal model led the group to do a pilot clinical trial of lithium in adult patients with fragile X syndrome and found measurable improvements in behavior and function after 2 months of open-label lithium treatment (Liu & Smith, 2014). The subjects had improvement in ADHD symptoms, aggression, vocalizations, self-abuse, work refusal, outbursts, mood swings, tantrums, and other fragile X syndrome-related behaviors. Another study showed that 18% of males and 11% of females with fragile X syndrome were receiving medication for mood swings; by age 20, the rates were 20% of males and 15% of females (Bailey et al., 2012).

At the time of this book's publication, no antiepileptic medications are approved for the treatment of bipolar disorder in children and adolescents. However, the antipsychotic aripiprazole is approved for bipolar disorder as monotherapy and in combination with both lithium and valproic acid.

Stimulants and Atomoxetine Stimulants of both the amphetamine and methylphenidate classes are first-line treatments for ADHD (see Chapter 19), and, as discussed in Box 27.9, research on the long-term efficacy and safety of such medications is ongoing. Both

BOX 27.8 EVIDENCE-BASED PRACTICE

Lithium to Treat Bipolar I Disorder in Children

Lithium has been approved by the U.S. Food and Drug Administration to treat bipolar I disorder in children over the age of 12. However, there are limited studies that have evaluated its effectiveness and safety in children. Findling and colleagues (2015) found that lithium was superior to placebo in reducing manic symptoms and generally well tolerated in children ages 7–17. However, further research is needed to determine the long-term safety and efficacy of lithium to treat bipolar I disorder in children.

BOX 27.9 EVIDENCE-BASED PRACTICE**Methylphenidate to Treat ADHD in Young Children**

Methylphenidate was first created and marketed as Ritalin in 1955 and is now a first-line treatment for attention-deficit/hyperactivity disorder (ADHD). However, whereas ADHD symptoms are often present during the preschool years, little is known about the long-term efficacy and safety of methylphenidate use for children in this age group (Vitiello et al., 2015). The Preschool ADHD Treatment Study (PATS; Greenhill et al., 2006) found immediate-release methylphenidate to be effective in treating ADHD in preschool-age children. A 6-year follow-up study of this population found that two thirds of this group continued using the stimulant medication, one quarter of the children discontinued pharmacotherapy, and 13.4% of the children were taking an antipsychotic medication. In addition, antipsychotic use was associated with the presence of a pervasive developmental disorder (Vitiello et al., 2015). This research adds to the limited data on long-term pharmacological treatment of children diagnosed with and treated for ADHD as preschoolers.

families of drugs now have long-acting preparations available that can improve control of ADHD symptoms throughout the day. Side effects include loss of appetite, insomnia, tics, headache, and gastrointestinal side effects (Pearson et al., 2003). The use of atomoxetine has been studied in children with ADHD (Harfterkamp et al., 2012) and ASD and has been found to control hyperactive/impulsive symptoms with an effect similar to methylphenidate (Clemow, Bushe, Mancini, Ossipov, & Upadhyaya, 2017; Gayleard & Mychailyszyn, 2017; Harfterkamp et al., 2012; Harfterkamp et al., 2013; Savill et al., 2015; Shang, Pan, Lin, Huang, & Gau, 2015).

Polypharmacy One of the biggest concerns as youth with intellectual disability become adults is the risk of polypharmacy, the concurrent use of multiple drugs to treat a disorder. Although there is limited research on its safety and effectiveness, polypharmacy—particularly in antipsychotic medications—is common in children (Comer, Olfson, & Mojtabai, 2010; Toteja et al., 2014).

Once medications are added, it becomes very difficult to remove them even when efficacy is not noted. One study involving a chart audit of 517 patients presenting to a specialized psychiatric outpatient clinic found that 70% of the patients were receiving at least one psychotropic medication and 22% had psychotropic polypharmacy (Lunsky & Modi, 2017). Polypharmacy use was associated with female gender, placement in a supervised residential setting, and having more than two psychiatric diagnoses. Another study of 231 patients found even a higher rate of polypharmacy (45%), especially when associated with a dual diagnosis (Hobden, Samuel, LeRoy, & Lindsay, 2013). Further research is necessary to determine the long-term safety

and tolerability of polypharmacy in children. This is important for children with intellectual disabilities, as these individuals are at greater risk of polypharmacy as they enter adulthood.

SUMMARY

- Children with developmental disabilities are at higher risk than their typically developing peers of developing psychiatric and behavioral disorders at some time during their childhood or adolescence.
- By being aware of the possibility of psychiatric disorders that can affect a child's behavior, parents, educators, and clinicians can identify problems early and intervene.
- Early intervention leads to more rapid resolution of difficulties and allows children to function more effectively and happily at home, at school, and in the community.

CHAPTER 28

Sleep Disorders

Judith Owens and Miriam Weiss

Upon completion of this chapter, the reader will

- Describe the clinical presentation and management of pediatric insomnia
- Outline a therapeutic approach to delayed sleep–wake phase disorders
- List the common features of disorders of arousal
- List pediatric populations at increased risk for sleep-disordered breathing
- Describe key causal factors in restless leg syndrome/periodic limb movement disorders

Sleep problems and disorders are some of the most common complaints brought to the pediatrician and sometimes the most difficult to resolve. In children with developmental disabilities, these issues tend to be even more common. This chapter discusses a range of sleep disorders including insomnia, circadian rhythm disorders, disorders of arousal, sleep-disordered breathing/obstructive sleep apnea (OSA), and movement-related disorders in sleep.

SLEEP ARCHITECTURE

The three categories of sleep stages include wake, non-rapid eye movement (REM) sleep, and REM sleep. The second category, non-REM sleep, is a time of low brain activity and can be divided into three stages of sleep. Stage 1 of non-REM sleep occurs at sleep–wake transitions, comprises 1%–3% of the total sleep period, and can include a normal phenomenon called hypnic jerks

or sleep starts. Stage 1 sleep is the easiest from which to awaken. Stage 2 sleep comprises the majority of the sleep period (approximately 50%) and is distributed across the whole night. Stage 3, deep sleep or slow-wave sleep, from which it is most difficult to awaken, occurs predominantly in the first half of the night and comprises 25% of the sleep period. The third category, REM sleep, also known as dream sleep, occurs largely during the second half of the night and increases in duration and intensity in the early morning hours; it comprises about 25% of the total sleep period.

During the typical four to eight sleep cycles, stages progress from non-REM sleep to REM sleep over about 90–110 minutes, with multiple brief arousals followed by a rapid return to sleep. Younger children have shorter sleep cycles and thus have more frequent arousals during the night. In addition, it should be noted that the normal percentages of the sleep stages listed above are typical for older children and adolescents;

for example, the percentage of slow-wave sleep is much higher in infants and younger children and declines in the second decade of life. Finally, different sleep disorders may be linked to specific sleep stages; for example, partial arousal parasomnias (sleep walking and night terrors) arise out of slow-wave sleep and thus mostly occur in the first part of the night (Mindell & Owens, 2015), and sleep-disordered breathing is often worse during REM sleep.

SLEEPING PATTERNS

The amount and distribution of sleep requirement over 24 hours also changes from infancy to adolescence and with a good deal of individual variability. With advances in circadian science, there is now emphasis on both optimal sleep duration and the timing of the sleep period. The time to sleep, or sleep onset latency, typically remains similar with an average of 15–30 minutes throughout the lifespan. Wake time after sleep onset can range from 10–30 minutes, and there can be as many as two dozen brief awakenings across the night. Newborns through 2 months of age require an average of 14 hours of sleep per 24 hours and 1–2 hours of wake time between day and nighttime sleep periods. By 6 months of age, infants do not require feeding during the sleep period and have consolidated their sleep into a 9- to 12-hour sleep period, optimally between 6:30 p.m. and 6:30 a.m. Infants aged 2–12 months require an average of 12–16 hours of sleep, including naps. Naps decrease from four to two per 24 hours during this age range. Children who are 1–2 years old require an average of 11–14 hours of sleep, including one to two naps averaging 2–3 hours in length, with a shift from two to one nap between 18–24 months. Children who are 3–5 years old require an average of 10–13 hours of sleep, and their naps will decrease from one nap to no naps during this age range. By 5 years of age, the majority of children have given up napping (Crosby, LeBourgeois, & Harsh, 2005). Children 6–9 years of age require an average of 10–12 hours of sleep, with a sleep period between 7:30 p.m. and 7:30 a.m.; 10–12 year olds require 10–11 hours, with a sleep period ranging from 8:30 p.m. to 7:30 a.m.; adolescents ages 13–15 require 9–10 hours of sleep, with a sleep period between 9:30 p.m. and 7:30 a.m.; and 16–20 year olds require 8–9.5 hours of sleep, with an optimal sleep period between 10:30 p.m. and 8:00 a.m. (Mindell & Owens, 2015).

Especially in children with developmental disabilities, more than one sleep disorder can present simultaneously. The following case study illustrates both the complexity of presenting complaints and the importance of taking a complete sleep history.

■ ■ ■ CASE STUDY

Will is a 10-year-old boy who was born with trisomy 21 (Down syndrome). He has limited expressive language skills, although his family is able to interpret most of his verbalizations. Will is pleasant and loving with others, and he enjoys listening to music, watching videos, and looking through comic books. Will also can be oppositional, although his parents have learned that talking to him in a quiet voice and using simple commands are often effective.

Will was diagnosed several years ago with severe OSA, which was documented on an overnight sleep study (polysomnogram), and he subsequently had an adenotonsillectomy (AT). Unfortunately, his postoperative polysomnogram continued to demonstrate severe OSA. His clinical symptoms included loud snoring, witnessed apneas, gasping, choking, restless sleep, sitting up to sleep, and daytime sleepiness. Will has a positive family history of OSA, environmental allergies, obesity, and mild hypothyroidism.

Some nights, Will refuses to go to bed and instead requests to watch TV in the living room. If he is not allowed to watch TV, he will get very upset, cry, and have a temper tantrum. As a result, his parents often give in and allow him to fall asleep on the couch with the TV on. Other nights he will fall asleep at bedtime but will awaken in the middle of the night and get up to watch TV, walk around the house, or get a snack from the kitchen. His mother is exhausted and does not always stay awake until he falls asleep. She often is not aware of his night wakings until she sees evidence the following morning (e.g., cupboards open and food remnants in the kitchen). She is concerned about possible safety issues resulting from his walking around the home unsupervised in the middle of the night. A behavioral therapist has recently started working with Will and his parents. The therapist has been working on setting appropriate limits with Will, and the parents have been open to these suggestions.

Thought Questions:

What are risk factors for obstructive sleep apnea? What are treatment options for children with obstructive sleep apnea who are not candidates for surgical intervention? What are possible interventions for managing insomnia in children with developmental delay?

INSOMNIA

Insomnia is broadly defined as having persistent difficulties with initiating and/or maintaining sleep despite an adequate opportunity to do so. In the younger child, insomnia typically presents as bedtime resistance and/or frequent night wakings, both of which usually require parental intervention. Older children may also

complain of difficulty falling asleep or prolonged night wakings. In these instances, parents may not necessarily be aware of these issues (Meltzer & Mindell, 2014).

Insomnia results in daytime impairments, including daytime sleepiness, irritability and mood disturbances, impaired attention and cognition, behavioral dysregulation, poor school performance, and negative social interactions (American Academy of Sleep Medicine, 2014). Insomnia and poor/insufficient sleep are also associated with negative health outcomes, such as obesity and metabolic dysfunction. There are also mental health consequences, including an increased risk of depression, suicide, and self-harm behaviors (Meltzer & Mindell, 2014). Finally, insomnia has a substantial negative impact on the parents and caregivers in regard to their own sleep, daytime function, and stress levels (Honaker & Meltzer, 2014).

Children with developmental disorders are particularly likely to experience and are prone to the adverse effects of sleep dysfunction. For example, children with autism may experience declines in verbal and socialization skills and poor adaptive functioning. Children with attention-deficit/hyperactivity disorder (ADHD) and sleep problems have an increased frequency of externalizing behaviors, oppositional behavior, and depressive symptoms (Maski & Owens, 2016).

Prevalence and Epidemiology

Insomnia occurs in 26%–32% of typically developing children. The prevalence of insomnia in adolescence is estimated to be between 3% and 12%, with a higher frequency typically reported in girls (American Academy of Sleep Medicine, 2014). The prevalence of insomnia is also significantly higher in special needs populations. For example, the rates of insomnia in children with autism is estimated to be 53%–78% (Malow et al., 2012). The sleep initiation type of insomnia is particularly common in children with ADHD (Miano et al., 2016). Sleep initiation and sleep maintenance are also common sleep concerns in children with cerebral palsy (Angriman, Caravale, Novelli, Ferri, & Bruni, 2015).

Etiology and Associations with Specific Developmental Disabilities

The classic “3 P” model of insomnia in adults has important potential parallels in children, including those with special needs. The first “P,” *predisposing* factors, includes 1) genetic predisposition, 2) underlying medical issues (e.g., chronic pain, breathing difficulties, concurrent medications, or immobility; American Academy of Sleep Medicine, 2014), 3) mental health issues,

4) child temperament, and 5) intellectual disability. For instance, co-occurring sleep disorders described later, such as circadian misalignment, restless leg syndrome, and OSA, may be contributory to insomnia. Environmental factors such as limited living space and unstable home situations may also play a role. The second “P,” *precipitating* factors, includes stressful life events such as relocation, parental separation, a new infant in the family, the death of a loved one, or even a move to a new school environment. The third “P,” *perpetuating* factors, includes 1) parenting practices, such as a caregiver’s prolonged presence at sleep onset; 2) reactive co-sleeping (i.e., as a response to sleep or health problems rather than a “lifestyle choice”); and 3) inappropriate limit setting. Additional perpetuating factors that have been linked to sleep disturbance include a later bedtime (after 9 p.m.), caffeine consumption, and electronic use during the sleep period (Honaker & Meltzer, 2014).

Insomnia is particularly likely to be of multifactorial origin for children with developmental disorders, such as autism and ADHD. These factors include 1) behavioral issues intrinsic to autism such as repetitive, self-injurious, and ritualistic behaviors, limited communication skills, and responsiveness to social cues; 2) medical issues (e.g., gastrointestinal problems or seizures); 3) psychiatric comorbidities such as anxiety; and 4) biological/circadian factors, such as alterations in normal melatonin receptors or release (Malow et al., 2012). While children with intellectual disabilities overall have an increased prevalence of sleep problems, they are particularly vulnerable to insomnia (Hollway, Aman, & Butter, 2013).

Several studies have shown that children with ADHD may have a delayed release of evening melatonin, which contributes to prolonged sleep onset. In addition, medications used to treat ADHD, such as extended-release psychostimulants, may play a role in insomnia, although the evidence is mixed. Access to electronic media devices also has to be taken into account, as they emit bright light that can affect the body’s production of melatonin, delaying sleep onset. As children with ADHD and autism tend to spend more time with electronic media devices than typically developing children, they may be more prone to the sleep-disrupting effects of these blue light-emitting devices (Maski & Owens, 2016).

While insomnia is overall more common in children with developmental and intellectual disabilities, various presentations of insomnia are especially common in several genetic syndromes (see Appendix B). These notably include Smith-Magenis syndrome and Rett syndrome, as well as Williams syndrome, Angelman syndrome, Down syndrome, and fragile X syndrome. Acquired neurodevelopmental disorders, such as fetal

alcohol spectrum disorder and cerebral palsy, also have an increased prevalence of insomnia. Many of these children have multiple sleep complaints that tend to be more severe, more refractory to treatment, and more likely to relapse compared with typically developing children.

Diagnosis and Clinical Manifestations

Insomnia in children is defined as the presence of significant difficulty in initiating or maintaining sleep. Chronic insomnia disorder is defined as symptoms occurring at least three times a week and being present for at least 3 months. Short-term insomnia disorder is present for less than 3 months (American Academy of Sleep Medicine, 2014). Presenting symptoms must also be associated with at least one of the following daytime impairments: fatigue, inattention, difficulty with concentration, memory impairment, mood disturbance, daytime sleepiness, academic concerns, or impairment of relationships with family or peers (American Academy of Sleep Medicine, 2014).

Behavioral insomnia in younger, typically developing children, as well as children with developmental disabilities (i.e., does not result primarily from physical factors such as discomfort or medication), may be further categorized as primarily due to inappropriate sleep onset associations, inadequate caregiver limit setting,

or both. In the former situation, the child has learned to fall asleep at bedtime under specific conditions that typically require caregiver presence (i.e., being rocked or fed); in the absence of those same conditions following normal night wakings, the child is unable to fall back to sleep independently (i.e., without caregiver intervention), resulting in prolonged night wakings. Limit-setting issues, often involving inconsistent or even nonexistent bedtimes, lack of a bedtime routine, and failure to enforce appropriate nighttime behavior, can result in bedtime resistance and sleep-onset delay as well as prolonged night wakings.

Monitoring, Screening, and Evaluation

The first step in assessment for sleep problems involves general screening for a variety of sleep disorders during clinical encounters. The BEARS tool (which has both a parent and child report component) can be used in clinical settings to screen for the most common childhood sleep complaints. BEARS is an acronym for **B**edtime problems, **E**xcessive daytime sleepiness, **A**wakenings during the night, **R**egularity and duration of sleep, and **S**nororing. It has been shown to elicit more information than a single general question, such as “Does your child have any sleep problems?” (see Figure 28.1; Owens & Dalzell, 2005). Other validated

The “BEARS” instrument is divided into five major sleep domains, providing a comprehensive screen for the major sleep disorders affecting children in the 2-to-18-year-old age range. Each sleep domain has a set of age-appropriate “trigger questions” for use in the clinical interview.

B = Bedtime problems

E = Excessive daytime sleepiness

A = Awakenings during the night

R = Regularity and duration of sleep

S = Snoring

Examples of developmentally appropriate trigger questions:

	Toddler/preschool (2–5 years)	School-age (6–12 years)	Adolescent (13–18 years)
Bedtime problems	Does your child have any problems going to bed? Falling asleep?	Does your child have any problems at bedtime? (P) Do you have any problems going to bed? (C)	Do you have any problems falling asleep at bedtime? (C)
Excessive daytime sleepiness	Does your child seem overtired or sleepy a lot during the day? Does she still take naps?	Does your child have difficulty waking in the morning, seem sleepy during the day, or take naps? (P) Do you feel tired a lot? (C)	Do you feel sleepy a lot during the day? In school? While driving? (C)
Awakenings during the night	Does your child wake up a lot at night?	Does your child seem to wake up a lot at night? Any sleepwalking or nightmares? (P) Do you wake up a lot at night? Have trouble getting back to sleep? (C)	Do you wake up a lot at night? Have trouble getting back to sleep? (C)
Regularity and duration of sleep	Does your child have a regular bedtime and wake time? What are they?	What time does your child go to bed and get up on school days? Weekends? Do you think he/she is getting enough sleep? (P)	What time do you usually go to bed on school nights? Weekends? How much sleep do you usually get? (C)
Snoring	Does your child snore a lot or have difficult breathing at night?	Does your child have loud or nightly snoring or any breathing difficulties at night? (P)	Does your teenager snore loudly or nightly? (P)

(P) Parent-directed question

(C) Child-directed question

Figure 28.1. BEARS sleep screening algorithm. (From Mindell, J. A., & Owens, J. A. (2015). *A clinical guide to pediatric sleep: Diagnosis and management of sleep problems* [3rd ed.]. Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins; reprinted by permission.)

subjective (caregiver report) measures that can be utilized include several sleep questionnaires validated in different age groups (e.g., the Brief Infant Sleep Questionnaire, the Children's Sleep Habits Questionnaire, or the Children's Night Waking Behavioral Scale; Honaker & Meltzer, 2014). Importantly, the initial assessment should include queries regarding symptoms of other sleep disorders that may co-occur with primary insomnia and affect sleep onset (i.e., restless leg syndrome or circadian-based delayed sleep–wake phase disorder) or sleep maintenance (i.e., periodic limb movement disorder or OSA; Honaker & Meltzer, 2014).

Once a sleep concern has been identified, either through screening or a presenting complaint, a comprehensive sleep history includes an assessment of 1) the sleep environment; 2) bedtime routine; 3) sleep-onset associations (conditions required in order for the child to fall asleep at bedtime); 4) actual bedtime and fall asleep time; 5) **sleep onset latency** (the time to transition from lights out to sleep onset); 6) number, duration, and frequency of night wakings/call outs (important to differentiate full and parasomnia/partial awakenings from sleep; 7) the child's behaviors and parental response to night wakings; and 8) morning wake time.

Bedtimes and wake times should include both the average, range, and weekday/weekend variability. Daytime sleepiness in prepubescent children can be assessed by failure to awaken spontaneously at the required time (e.g., child needs multiple reminders), sleeping later when given the opportunity (e.g., on weekends), and signs of sleepiness (dozing off and yawning). Children older than 10 years of age can report daytime sleepiness and may have short and prolonged naps during the day. Sleepiness may present as well as hyperactivity, poor impulse control, inattention, and oppositional behavior.

A sleep log or diary is an essential tool for identifying variability in sleep patterns and quantifying sleep duration. It also helps circumvent the tendency of caregivers to report “last night's” sleep or “worst night's” sleep parameters. Generally recorded over a 2-week period, sleep logs provide detailed “real-time” information regarding 1) sleep onset latency, 2) number and duration of night wakings, 3) time in bed, 4) total sleep time, 5) sleep efficiency (time asleep/time in bed), 6) morning wake time, 7) nap timing and duration (Honaker & Meltzer, 2014), 8) mid-sleep time (a marker of chronotype), and 9) sleep–wake variability (both night-to-night and social jet lag–variability on weekdays versus weekends). In conjunction with a sleep diary, an actigraph (a sleep validated ambulatory accelerometer) can be worn to quantify these same parameters using a validated computer algorithm for activity. Because older children and caregivers may overestimate sleep parameters

(American Academy of Sleep Medicine, 2014), actigraphy can be a helpful tool for more objectively evaluating and monitoring insomnia (de Souza et al., 2003).

A much more extensive evaluation of sleep disorders involves polysomnography, as was done with the patient described in the case study at the beginning of this chapter. This is a comprehensive recording of the biophysiological changes that occur during sleep. The **polysomnogram** monitors brain activity (EEG), eye movements (EOG), muscle activity (EMG), and heart rhythm (ECG) during sleep. It should be noted that although the overnight in-lab polysomnogram is the gold standard for evaluation of OSA (i.e., loud nightly snoring or chronic mouth breathing) or periodic limb movement disorder (repeated flexion of the legs in sleep), it is seldom indicated in the evaluation of insomnia except in cases in which other symptoms suggestive of these other disorders co-exist.

Treatment, Management, and Interventions

Behavioral treatments are highly effective in improving both sleep-initiation and sleep-maintenance insomnia symptoms in children (Honaker & Meltzer, 2014). In younger children, the goals of these treatment strategies are to establish healthy bedtime routines and optimal sleep schedules and to optimize the drive to sleep and normal circadian rhythms. Some examples of evidence-based behavioral interventions in younger children include 1) unmodified extinction (e.g., “crying it out,” in which caregivers are instructed to ignore the child's protest behavior), 2) graduated extinction (which involves the parent gradually delaying their response to the crying child while providing reassurance with periodic “check-ins”), and 3) “bedtime fading” (which temporarily delays the child's bedtime to more closely approximate their actual fall asleep time, thus reducing sleep-onset latency and the opportunity for frequent “curtain calls”; Gradisar et al., 2016).

For older children, establishing a reward system for desirable bedtime/nighttime behavior can be very effective (e.g., the Bedtime Pass). Common pitfalls in establishing this program include failure to anticipate 1) an “extinction burst” (i.e., an increase in protest/tantrum behavior for several nights after the intervention is implemented) and 2) the “intermittent reinforcement” paradigm, in which the caregiver's failure to respond in a consistent manner to night wakings, for example, actually prolongs the child's problematic behavior.

Several prospective studies have failed to find significant long-term negative effects (i.e., up to 5 years post-treatment) of these behavioral interventions on cognitive and emotional development, behavior, stress levels, psychosocial functioning, and parent–child relationships

(Price, Wake, Ukoumunne, & Hiscock, 2012). It is also worth emphasizing that these same strategies, with some modifications, can be very effective in addressing insomnia in special needs children (Grigg-Damberger & Ralls, 2013). Behavioral therapy approaches are more extensively discussed in Chapter 34.

Another approach to treatment involves cognitive behavioral therapy for insomnia (CBT-I). This includes implementing a multidimensional treatment approach, including 1) basic principles of good sleep hygiene; 2) restricted time in bed (including avoidance of napping); 3) stimulus control (reversing the conditioned association of being in bed with being awake); and 4) psychoeducation, relaxation techniques, and cognitive therapy (addressing maladaptive cognitions and “catastrophizing” about the consequences of insomnia). CBT-I can be very helpful in older children (especially those with comorbid anxiety) and adolescents (de Bruin, Bögels, Oort, & Meijer, 2015; Maski & Owens, 2016). A child with insomnia and developmental disabilities may also benefit from outpatient visits with a psychologist familiar with sleep disorders and treatment or a psychologist with a certification in behavioral sleep medicine (see Box 28.1).

While sleep-inducing medications are frequently used in clinical practice, especially for children with neurodevelopmental disorders, it should be emphasized that there are currently no medications approved by the U.S. Food and Drug Administration (FDA) for treatment of insomnia in children. The few published pediatric randomized controlled trials of either OTC or prescription sedative/hypnotics have overall demonstrated limited or no efficacy. Furthermore, safety profiles are largely absent for these medications in children. Therefore, medications should be used with caution and only in conjunction with behavioral strategies.

However, while further research is needed, especially regarding long-term safety, several clinical trials in both typically developing children and those with developmental disabilities (i.e., autism and ADHD) have suggested that the synthetic form of the pineal gland hormone melatonin may be an effective treatment for sleep-onset and possibly sleep-maintenance

(extended-release formulation) insomnia with few identified adverse effects (Maski & Owens, 2016). It should be noted that over-the-counter preparations of melatonin have been shown to be frequently unreliable in terms of actual concentration, and therefore use of pharmaceutical-grade melatonin is recommended. Further research is needed in identifying precipitants of and risk factors for childhood insomnia and evidence-based behavioral best-fit management options.

Talking Points

1. Insomnia is highly prevalent in children with developmental disorders and can be screened for using validated sleep questionnaires.
2. Utilizing the “3 P” method can help identify factors contributing to insomnia (predisposing, precipitating, and perpetuating factors).
3. Behavioral treatments are highly effective in managing insomnia in children, including those with neurodevelopmental disorders.

CIRCADIAN RHYTHM DISORDERS

Circadian rhythm sleep–wake disorders are caused by alterations of the circadian system or a misalignment of the internal circadian rhythm and societal demands (e.g., early school start time for adolescents). This misalignment most often occurs between an individual’s internal rhythm and the required timing of environmental demands such as work or school (American Academy of Sleep Medicine, 2014). Circadian rhythm disorders include 1) delayed sleep–wake phase disorder, 2) advanced sleep–wake phase disorder, 3) irregular sleep–wake rhythm disorder, and 4) non-24-hour sleep–wake rhythm disorder. Symptoms must be present for at least 3 months to receive any of these diagnoses (American Academy of Sleep Medicine, 2014).

An important risk factor for circadian rhythm disorders is a circadian preference or “chronotype” at either

BOX 28.1 INTERDISCIPLINARY CARE

The Role of the Behavioral Psychologist

A behavioral psychologist with certification in behavioral sleep medicine is an essential part of a sleep team. This behavioral psychologist evaluates and treats behavioral, psychological, and physiological factors that contribute to the etiology and complicate the management of sleep disorders. However, due to the limited number of psychologists within this specialty, it is beneficial to align the sleep team with a psychologist who can address behavioral concerns that contribute to sleep disorders.

extreme (i.e., persistent and intractable “eveningness” or, less frequently, “morningness”). The most common presenting symptoms of circadian rhythm sleep–wake disorders are difficulty initiating sleep (delayed sleep phase) in the early evening and difficulty waking in the morning, bedtime time and early morning waking (advanced sleep phase), and highly irregular or rapidly changing sleep patterns. These symptoms are associated with excessive sleepiness and consequent impairment in social, educational, mental, or physical functioning (American Academy of Sleep Medicine, 2014).

Delayed sleep–wake phase disorder involves a significant delay in sleep time and wake time in comparison to the timing required to fulfill educational and social demands (Auger et al., 2015). It occurs most frequently in adolescents and young adults, as there is a well-established biological propensity for a sleep phase delay starting at puberty and ending in the mid-20s for most individuals. Over time, this may lead to chronic tardiness, school avoidance, and poor academic performance, or even dropping out of school. It also may be associated with mood changes and impaired social interactions. Sleep quantity and quality are typically normal when the child is allowed to sleep on his/her own delayed schedule (American Academy of Sleep Medicine, 2014). Some recent evidence, however, suggests that an extreme evening chronotype may in and of itself be associated with physical and mental health impairments and increased risk-taking behaviors (American Academy of Sleep Medicine, 2014; Short, Gradisar, Lack, & Wright, 2013).

Advanced sleep–wake phase disorder includes the early timing of sleep onset and sleep offset. This tends to be more common in young children and is defined as difficulty staying awake during the evening hours and a wake time that is undesirably early in relation to caregiver and family schedules (American Academy of Sleep Medicine, 2014; Auger et al., 2015).

Irregular sleep–wake rhythm disorder is quite rare and is characterized by a recurrent pattern of irregular sleep and wake episodes within a 24-hour period. This is characterized by symptoms of insomnia at night, excessive sleepiness during the day, or both (American Academy of Sleep Medicine, 2014). Sleep and wake episodes are fragmented, with the longest sleep period typically less than 4 hours (American Academy of Sleep Medicine, 2014; Auger et al., 2015).

Non-24-hour sleep–wake rhythm disorder, which occurs largely in blind patients and is very rare in sighted individuals, is diagnosed when the patient does not have a 24-hour dark-light cycle, resulting in sleep–wake patterns that show a progressive delay or advance over subsequent days and nights. These sleep–wake schedules gradually shift, with the child

alternately experiencing daytime sleepiness and nighttime insomnia (Auger et al., 2015).

Prevalence and Epidemiology

The prevalence of delayed sleep–wake phase disorder in adolescents and young adults is estimated to be between 7% and 16% (American Academy of Sleep Medicine, 2014). While most adolescents experience a normal biological shift (delay) of several hours, with a propensity for a later bedtime and wake time around pubertal onset, in some individuals this “eveningness” tendency is exaggerated. The prevalence of advanced sleep–wake phase disorder and irregular sleep–wake rhythm disorder in the pediatric population has not been extensively documented but is encountered relatively rarely, even in sleep specialty clinics. The prevalence of non-24-hour sleep–wake rhythm disorder in blind individuals is thought to be over 50%; however, data on prevalence in other pediatric populations has not been well studied (American Academy of Sleep Medicine, 2014).

Etiology and Associations with Specific Developmental Disabilities

There are multiple reasons why children with developmental disabilities are at greater risk for circadian rhythm disorders. Children with ADHD may be at higher risk due to intrinsic delayed melatonin onset (American Academy of Sleep Medicine, 2014). Some children with autism have been found to have underlying alterations in the release and metabolism of melatonin and in melatonin receptors, with resulting irregular sleep patterns and either delays in sleep onset or advances in sleep offset (American Academy of Sleep Medicine, 2014). It should be noted that in addition to a genetic predisposition, environmental factors may exacerbate sleep disorders as previously discussed (American Academy of Sleep Medicine, 2014).

Diagnosis and Clinical Manifestations

A sleep log or diary and actigraphy for at least 2 weeks are necessary for assessing sleep–wake patterns in a child suspected of having a circadian rhythm sleep–wake disorder. The sleep log and actigraphy will show an average mid-sleep time (middle of the sleep period) and delayed sleep onset and offset of greater than 2 hours compared with socially acceptable times (American Academy of Sleep Medicine, 2014) or times that conflict with school or other activities. There are also several scales that are appropriate for use in the pediatric population to assess chronotype, including the Morningness-Eveningness

Scale for Children and the Munich Chronotype Questionnaire (Carskadon, Vieira, & Acebo, 1993; Roenneberg, Wirz-Justice, & Mellow, 2003).

Monitoring, Screening, and Evaluation

The sleep log and actigraphy are used to assess treatment response to changes in sleep–wake patterns during each phase of the management process. Evaluation of daytime sleepiness with surveys such as the Epworth Sleepiness Scale (Johns, 1991), periodic assessment of changes in mood, and logs of school attendance and performance are all important to monitor treatment outcomes.

Treatment, Management, and Interventions

The principle components of management of patients with delayed sleep–wake phase disorder include 1) gradually advancing sleep–wake schedules with progressively earlier morning wake times, 2) avoiding evening video bright light close to bedtime (to avoid suppression of melatonin release), 3) increasing morning light exposure, 4) administering melatonin in the evening, and 5) providing CBT-I.

For patients with delayed sleep–wake phase disorder, referral to a sleep specialist should be considered, especially in cases where there is significant school avoidance or a mood disorder. Typically, patients are instructed to successively advance their wake time first and then bedtime until the target sleep schedule is reached. Chronotherapy or successive *delays* in bedtime and wake time by 2–3 hours each day (done to move the patient “forward around the clock”) may be employed in cases of severe phase delay; however, this technique is challenging to implement (Auger et al., 2015). Timed morning light exposure should occur at rise time and then may be moved successively earlier, although some care needs to be exercised when a patient has a severe phase delay. This can be provided by natural light or a “bright” light (2,500 to 10,000 lux) via a commercial light box device. Melatonin may be given as a small “chronobiotic” dose (e.g., 0.5 mg to avoid inducing sleepiness) 5–7 hours before sleep onset and/or as a “hypnotic” dose of 3 to 5 mg 30 minutes before bedtime.

A more systemic approach to the general, biologically based tendency toward eveningness in adolescents involves delaying middle and high school start times to allow for adequate sleep and avoid circadian misalignment (a phenomenon also known as “social jetlag”; Adolescent Sleep Working Group, Committee on Adolescence, & Council on School Health, 2014). Chronic sleep deficiency related to early start times (i.e., earlier than 8:30 a.m.) has been shown to

be associated with a multitude of educational, mental health, and physical concerns, including drowsy driving, increased risk for obesity, increase in risk-taking behaviors, depressed mood, and lower academic performance. Delayed start times have been associated with improvements in these health, safety, and functional outcomes (Owens & Weiss, 2017). A number of school districts have moved high school start times later as a result of these findings.

Suggested treatment for advanced sleep–wake phase disorder includes evening light therapy, planned sleep schedules with moving bedtime later, and timed melatonin administration in the morning (Auger et al., 2015). Less well-substantiated treatment options for irregular sleep–wake rhythm disorder and non-24-hour sleep–wake rhythm disorder include melatonin administration in the evening, timed light exposure, and changes in sleep–wake scheduling (Auger et al., 2015).

Circadian rhythm sleep–wake disorders that are caused by rigid and more extreme chronotypes are often chronic conditions that are more difficult to treat, while a weaker chronotype, poor sleep hygiene, and secondary gain (school avoidance or social anxiety) are more amenable to treatment when the child is motivated and the family is supportive. For treatment-resistant cases, referral to a sleep specialist is strongly recommended.

Talking Points

1. Children with developmental disabilities may be at higher risk for circadian rhythm disorders, misalignment of the circadian system, and societal demands due to alterations in release or metabolism of melatonin.
2. Delayed sleep–wake phase disorder can be managed with behavioral interventions, including gradual advancement of sleep–wake schedules, avoiding bright light in the evening, increasing morning light exposure, administering melatonin in the evening, and providing CBT-I.

DISORDERS OF AROUSAL/ PARTIAL AROUSAL PARASOMNIAS

Parasomnias are defined as undesirable events or experiences that occur during entry into, arousal from, or within sleep. Some occur during non-REM, and others occur during REM sleep (when dreaming occurs). Partial arousal parasomnia occurs primarily during non-REM slow-wave sleep; it is referred to as a disorder of arousal or partial arousal and includes confusional arousals, sleepwalking (somnambulism), and

sleep terrors. Parasomnias associated with REM sleep include nightmares and sleep paralysis.

As noted earlier, disorders of arousal occur almost exclusively during slow-wave or “deep” sleep and thus usually occur within a few hours after sleep onset. The episodes may vary from a few minutes to as long as 30–40 minutes and are characterized by amnesia for the event. During an episode, children or adolescents may have the appearance of being awake, and most children actively avoid comfort or soothing and are very difficult to awaken. Finally, because the relative percentage of slow-wave sleep is highest in childhood and drops fairly dramatically in the second decade of life, disorders of arousal are most common in young children, and their prevalence declines with increasing age (Mindell & Owens, 2015).

Prevalence and Epidemiology

Confusional Arousals Because confusional arousals may not be recognized or brought to medical attention, the prevalence is difficult to determine but has been estimated to be around 15%–20% in children ages 3–13 years. Onset is typically before age 5 and can occur as early as the first year of life, although they may not be recognized as such. Confusional arousals may co-occur with sleepwalking and sleep terrors.

Sleepwalking Sleepwalking is a common childhood phenomenon. It is estimated that 15%–40% of children sleepwalk on at least one occasion; however only about 3%–4% of children have frequent episodes. As with other disorders of arousal, sleepwalking usually abates by adolescence. Sleepwalking prevalence may be underestimated because episodes may be unobserved or misinterpreted as night wakings (many children have both). Onset of episodes is usually between ages 4–6 years, and peak occurrence is between ages 8–12 years. About one third of sleepwalkers have episodes for about 5 years, and a minority (10%) will continue to sleepwalk for up to 10 years (Mindell & Owens, 2015).

Sleep Terrors Less common than confusional arousals and sleepwalking, sleep terrors are experienced by about 1%–6% of children, primarily during the preschool and elementary school years. They have a similar age of onset as sleepwalking, and both types of events may co-occur in the same child. In fact, the prevalence of sleep terrors in children who sleepwalk is about 10%. The frequency of sleep terror episodes is often highest at the onset; frequency also tends to be higher with younger age of onset. It almost always

disappears by adolescence. There appears to be little gender difference in the prevalence of disorders of arousal.

Etiology and Associations with Specific Developmental Disabilities

There is sometimes a suggestion of a genetic component to disorders of arousal. The prevalence is approximately 10 times greater in children with a family history of sleepwalking; 45% if one parent has the disorder, and 60% if both parents are affected versus 5% in the general population. Disorders of arousal appear to be more common in individuals with migraine headaches and Tourette syndrome, possibly related to alterations in serotonin metabolism.

Disorders of arousal occur almost exclusively during slow-wave sleep. Because there is an increased homeostatic drive for slow-wave sleep and insufficient sleep often results in a rebound compensatory increase in slow-wave sleep, not getting enough sleep increases the likelihood that a partial arousal parasomnia episode will occur in a susceptible individual. The classic example is a sleepwalking episode occurring after a sleepover with friends that resulted in reduced sleep; high sleep drive due to changes in the sleep schedule and other sleep disruptors, including another sleep disorder, a different environment, illness, or sleeping with a full bladder, may trigger an episode. Noise, caffeine consumption, or a shift to a lighter stage of sleep may all be event triggers as well. Stress and, in rare cases, trauma may cause partial arousal parasomnia, but they are not primary due to an underlying psychological problem or central nervous system disorder.

Finally, although general disorders of arousal do not appear to be significantly increased in children with developmental disorders, they may have a higher prevalence of concurrent primary sleep disorders, such as OSA and periodic limb movement disorder, which increase arousals and trigger events. It should also be noted that while exceedingly rare, nocturnal seizure disorders should be considered as a differential diagnosis (Maski & Owens, 2016).

Diagnosis and Clinical Manifestations

Confusional arousals involve disorientation and unresponsiveness to the environment. They may start with the child sitting up in bed, involve thrashing around, and be accompanied by agitation and combative behavior. If the child gets out of bed, then it is considered a sleepwalking event.

Sleepwalking episodes can begin with confusional arousals, although they can also begin with a

child rising from bed. During sleepwalking episodes, the child appears confused or dazed, the eyes are usually open, and she may mumble or give inappropriate answers to questions. Occasionally, a sleepwalking child may appear agitated. A sleepwalker may engage in a range of behavior, such as urinating in a closet, walking calmly to the parents' bedroom, going downstairs, cooking or eating, and leaving the house or stepping through a window onto a balcony or rooftop. Sleepwalking can occur infrequently or on a nightly basis. Injuries can occur during sleepwalking, ranging from bruises to more serious injuries related to leaving the home.

Sleep terrors are dramatic events and, as such, can be highly distressing to caregivers. The child, however, is totally unaware of his or her behavior, and these episodes are much worse to watch than to experience. Sleep terrors usually have a sudden onset, and the child's appearance during one of these episodes is that of extreme agitation, fright, and confusion, often involving crying and/or screaming. Extreme physiologic arousal is common (i.e., hyperventilation, rapid heart rate, excessive sweating, and dilated pupils). The episodes can occur during any sleep period, including naps, but they are usually in the first third of the night when slow-wave sleep predominates (Mindell & Owens, 2015).

Monitoring, Screening, and Evaluation

Having caregivers track the frequency and timing of events associated with disorders of arousal is critical in establishing the diagnosis and documenting a baseline of severity. This can be done in conjunction with a sleep diary to assess sleep duration. It is often also very helpful to ask parents to video record an event, as the verbal description may not include or distort important details such as the duration of the event and specific behaviors. Overnight polysomnography is not routinely ordered as part of the evaluation because these are episodic events and may not be captured on a single-night study. However, if there is a concern about sleep-disordered breathing, periodic limb movement disorder, or a question of nocturnal seizures as part of the differential diagnosis, an overnight sleep study may be appropriate (Maski & Owens, 2016).

Treatment, Management, and Interventions

With the exception of enhanced safety monitoring procedures in sleepwalking, the management of the different disorders of arousal is quite similar. Caregivers should be instructed to avoid waking the child during an episode, as this may increase agitation and prolong the event. The child should be gently guided back to bed. Avoidance of triggers such as insufficient sleep is key, as are other

sleep hygiene measures such as a regular sleep–wake schedule and avoiding caffeine. Safety measures include assuring that the caregiver will wake and observe the child, double-locking doors and windows, ensuring the safety of the sleeping environment (e.g., removing clutter on floors), attaching furniture to walls, and installing alarm systems or a bell attached to the bedroom door to alert caregivers (www.sleepwalkingsafety.com).

Scheduled awakenings are typically recommended only for frequent (i.e., nightly) events. These involve having the parent wake the child approximately 15–30 minutes prior to the time of night that the episode (or first episode in the event of more than one) typically occurs. This can be confirmed with a sleep diary. The caregiver is instructed to awaken the child on a nightly basis, just to the point of arousal (e.g., child changes position or mumbles). These nightly awakenings should be continued for 2–4 weeks.

Pharmacologic treatment is very rarely indicated except in cases of persistent, frequent episodes, particularly when there is a high risk of injury, aggressive behavior, or serious disruption to the family. The primary pharmacologic agents used are potent slow-wave sleep suppressants such as benzodiazepines and tricyclic antidepressants (see Appendix C). They typically require very gradual weaning to avoid a rebound increase in events (Mindell & Owens, 2015).

Outcomes

Most children naturally stop sleepwalking or experiencing sleep terrors during childhood, and almost all cases resolve spontaneously following puberty as a result of the associated dramatic decrease in slow-wave sleep. In those individuals whose episodes persist into adolescence and adulthood, awareness of potential triggers is important (e.g., inadequate and/or disrupted sleep and excessive caffeine consumption).

Talking Points

1. Parasomnias, including confusional arousals, sleepwalking, and sleep terrors, occur almost exclusively in slow-wave sleep within the first few hours after sleep onset and are characterized by disorientation and unresponsiveness and amnesia of the event in the morning by the child.
2. Insufficient sleep and sleep disruptors such as OSA are common contributors to parasomnias.
3. Management includes ensuring the child's safety, avoidance of triggers, and treating underlying disorders such as insufficient sleep or OSA.

SLEEP-DISORDERED BREATHING AND OBSTRUCTIVE SLEEP APNEA

Sleep-disordered breathing in children is characterized by an abnormal respiratory pattern during sleep. It encompasses a broad spectrum of respiratory disorders that occur across development, from neonates through adolescence. Types of obstructive sleep-disordered breathing include “primary” snoring, upper airway resistance syndrome, obstructive hypoventilation, and OSA (Mindell & Owens, 2015).

Primary snoring is typically defined as snoring without associated ventilatory abnormalities. However, habitual snoring indicates the presence of heightened *upper airway resistance*, and there is evidence that this snoring alone can be associated with an increased risk for adverse outcomes.

Obstructive hypoventilation is characterized by snoring, increased respiratory effort, and accumulation of carbon dioxide. OSA involves repeated episodes of prolonged partial or complete cessation of airflow due to complete and/or partial obstruction during sleep with continued or increased respiratory effort. These disruptions of airflow result in gas exchange abnormalities (i.e., mild to severe hypoxemia and hypercapnia) that contribute to the triggering of arousals that serve to increase upper airway patency. Intermittent hypoxemia, arousals, and recurrent sympathetic activation are thought to be the most significant contributors to the short- and long-term negative sequelae of OSA that include decrements in cardiovascular, metabolic, and neurocognitive function.

Prevalence and Epidemiology

Overall, it is estimated that about 10% of prepubertal children in the United States habitually snore, with 20% snoring occasionally. The prevalence of OSA is estimated to be in the range of 1%–5% (Marcus et al., 2012). Specific populations, however, appear to have a significantly higher prevalence, including African American children, younger children (ages 2–8 years) and boys (particularly after puberty), children with Down syndrome, and other patients with craniofacial anomalies.

Etiology and Associations with Specific Developmental Disabilities

In general terms, OSA results from an anatomically or functionally narrowed upper airway. This may be due to enlargement of the adenoids and tonsils, environmental allergies with nasopharyngeal edema, congenital syndromes impacting the craniofacial region,

gastroesophageal reflux, and obesity (Tan, Gozal, & Kheirandish-Gozal, 2013). Reduced upper airway tone may be present in children with neuromuscular disorders, cerebral palsy, and hypothyroidism, placing them at increased risk for OSA.

Decreased central ventilatory drive may be seen in a wide variety of CNS disorders, especially those affecting the brainstem. Obesity is an increasingly common risk factor for sleep-disordered breathing in the pediatric population. Children with syndromes characterized by obesity, such as Prader-Willi and Beckwith-Wiedemann, are at especially high risk. Children with Down syndrome are also high risk for multiple reasons, including truncal obesity, macroglossia, hypotonia, and hypothyroidism. Other contributory factors to sleep-disordered breathing in children include a history of prematurity, exposure to secondhand smoke, and a positive family history of OSA/snoring. See Table 28.1 for risk factors for pediatric sleep-disordered breathing (Owens, 2009).

Diagnosis and Clinical Manifestations

The core presenting symptoms of sleep-disordered breathing in children include loud habitual snoring with or without observed breathing pauses, chronic mouth breathing, restless sleep, and excessive sweating during sleep. Paradoxical movement of the chest wall and abdominal muscles during sleep may also be noted. It can be helpful for caregivers to videotape their child’s breathing during sleep to confirm these observations. Excessive daytime sleepiness is less common in children with sleep-disordered breathing compared

Table 28.1. Risk factors for pediatric sleep disordered breathing

Upper airway obstruction
Upper airway narrowing
Reduced upper airway tone
Adenotonsillar hypertrophy
Craniofacial anomalies
Trisomy 21
Hypotonia/neuromuscular disorders
Chronic allergies, asthma
Gastroesophageal reflux
Repaired cleft palate
Obesity
Family history
Prematurity at birth
Prior adenotonsillectomy

Revised from Owens, J. A. (2009). Neurocognitive and behavioral impact of sleep disordered breathing in children. *Pediatric Pulmonology*, 44, 417–422.

with adults, and it tends to occur in the setting of severe OSA and/or obesity. More common are behavior and academic problems. These include concerns about inattention, hyperactivity, impulsivity, and irritability, which may be the primary presenting complaints in children with OSA. In particular, many of the neurocognitive, mood-related, and behavioral manifestations of sleep-disordered breathing closely resemble those associated with ADHD. Secondary enuresis (bedwetting) and an increase in partial arousal parasomnias are less common associated symptoms (Tan et al., 2013).

Monitoring, Screening, and Evaluation

All children should be routinely screened for symptoms of sleep-disordered breathing during well-child doctor visits; a more focused exam and queries regarding potential risk factors should follow if symptoms are present. As parents do not necessarily associate behavioral and attention problems with OSA, a high index of suspicion should be maintained by the clinician. Children presenting with behavioral, mood, attentional, or academic concerns should be systematically screened for symptoms of and risk factors for OSA. Physical exam findings may include increased body mass index, systemic hypertension, adenoidal facies, “allergic shiners,” a small chin, swollen nostril turbinates (a shelf of bone covered by mucosa that protrudes into the breathing passage of the nose)/deviated septum, a high arched palate, and tonsillar enlargement.

The American Academy of Pediatrics (AAP) clinical practice guidelines for diagnosis and management of childhood obstructive sleep apnea syndrome (Marcus et al., 2012) recommend overnight in-lab polysomnography as the “gold standard” for the diagnosis of OSA, given that no combination of history and physical findings has been shown to be reliably predictive of significant pathology. Alternative diagnostic evaluations that are not validated and have various drawbacks but may be helpful in settings in which in-lab nocturnal polysomnography is not readily accessible include nocturnal pulse oximetry

or video recordings and a daytime nap (in infants) or ambulatory polysomnogram (Marcus et al., 2012). However, it should be noted that lack of evidence of sleep-disordered breathing resulting from any of these alternative studies in a symptomatic patient may represent a false negative, and thus a full polysomnogram is recommended.

Treatment, Management, and Interventions

There are presently no universally accepted guidelines regarding the indications for treatment and follow up of pediatric sleep-disordered breathing. The decision of whether and how to treat OSA in children is contingent on a number of parameters, including severity of polysomnographic study results, the likely cause of upper airway obstruction, duration of the disease, individual patient variables such as age (adult severity criteria may be applied to children ages 13 or older), and either the presence or risk for comorbid conditions (e.g., cardiovascular disease or metabolic syndrome). In the case of moderate to severe disease, the decision to treat is usually straightforward, and most pediatric sleep experts recommend that any child with an apnea index of greater than 5 per hour should be treated (Mindell & Owens, 2015).

Adenotonsillectomy (AT) is the most common treatment for pediatric OSA, and it, in turn, is the most common indication in the United States for tonsillectomy with or without adenoidectomy (see Box 28.2). It is the first-line treatment in any child with significant adenotonsillar enlargement, even in the presence of additional risk factors such as obesity. In uncomplicated cases, the success rate is about 80% in terms of resolution of symptoms (see Box 28.3). Risk factors for residual OSA include obesity, asthma, craniofacial anomalies, Down syndrome, and more severe sleep apnea. It is recommended that these children should be considered for a repeat postoperative polysomnogram, especially if symptoms persist. Other surgical procedures include removal of enlarged turbinates and nasal septal reconstruction (Marcus et al., 2013).

BOX 28.2 INTERDISCIPLINARY CARE

The Role of the Pediatric Otolaryngologists

Pediatric otolaryngologists provide expertise in the evaluation and surgical management of children with sleep disordered breathing. As adenotonsillar hypertrophy and other forms of nasopharyngeal obstruction are the most common contributors to obstructive sleep in children, collaboration with a pediatric otolaryngologist is essential.

BOX 28.3 EVIDENCE-BASED PRACTICE**The CHAT Study**

The Childhood Adenotonsillectomy Trial (CHAT) was a randomized controlled study of adenotonsillectomy versus watchful waiting in children with OSA. Published in 2013, it demonstrated normalization of polysomnographic findings in 79% of children who had an adenotonsillectomy for treatment of OSA with an obstructive apnea hypopnea index of greater than 2 per hour and less than 30 per hour. Interestingly, 46% of the children with OSA assigned to watchful waiting in place of adenotonsillectomy had resolution of polysomnographic abnormalities. There was no change in attention or executive function scores after adenotonsillectomy, but there was evidence of reported improvements in executive function and behavior after adenotonsillectomy as compared with the watchful waiting group.

Evidence-based nonsurgical treatment for OSA in children is largely targeted at reducing the obstruction and increasing upper airway patency and includes 1) weight management; 2) nasal steroids/leukotriene esterase

inhibitors (like Singulair used in asthma); 3) positional therapy (avoidance of the supine/back sleeping position); 4) oral appliances (mandibular advancement/palatal expansion; see Box 28.4); and 5) myofunctional therapy,

BOX 28.4 INTERDISCIPLINARY CARE**Dental Sleep Medicine**

Dental sleep medicine is playing an increasingly important role in the management of children with sleep-disordered breathing. Maxillofacial features contributing to obstructive sleep apnea may be correctible with oral appliances such as palatal expanders and mandibular advancement. Myofunctional therapy, often delivered under the supervision of a dental hygienist, uses exercises to target improper function of the tongue and facial muscles used for chewing and swallowing to improve upper airway patency.

which focuses on exercises to correct improper function of the tongue and facial muscles used for chewing and swallowing in order to improve upper airway patency (Camacho et al., 2015). Continuous or bilevel airway

pressure therapies are effective and well tolerated by some children who are not candidates for surgery. Education and gradual exposure to the therapy are recommended to improve tolerance and adherence (see Box 28.5).

BOX 28.5 INTERDISCIPLINARY CARE**Positive Airway Pressure**

Positive airway pressure (PAP) may be indicated in the child with obstructive sleep apnea who previously had adenotonsillectomy or does not have indication for tonsillectomy. This therapy is a noninvasive method of providing distending pressure to maintain a patent airway through a nasal or full-face interface securely attached to the head. A multidisciplinary sleep team, including sleep providers, pediatric sleep technicians, and sleep coordinators, can successfully help children use PAP therapy. The family and child require education and evaluation of preparedness for this therapy before initiation. Close follow-up of the child's compliance and tolerance to the PAP therapy device are important parts of the successful use of PAP therapy.

Outcomes

Studies that have examined changes in behavior and neuropsychological functioning in children following treatment for OSA have largely documented significant improvement in both short- and long-term outcomes. These have included decreases in daytime sleepiness and improvements in mood, behavior, academics, and quality of life. However, many studies have failed to find a dose-dependent relationship between OSA in children and specific neurobehavioral/neurocognitive deficits. This has led to speculation that other factors, including individual genetic susceptibility; environmental influences, such as allergen and pollution exposure; and comorbid conditions, such as obesity, shortened sleep duration, and the presence of other sleep disorders, may also influence outcome (Marcus et al., 2013).

Talking Points

1. OSA is characterized by repeated episodes of cessation of airflow due to obstruction resulting in gas exchange abnormalities.
2. In addition to loud snoring, pauses in breathing, and restless sleep, common symptoms in children can include inattention, hyperactivity, impulsivity, and irritability.
3. AT is the most common treatment for OSA; other management options include weight management, medication (i.e., nasal steroids and leukotriene esterase inhibitors), positional therapy, oral appliances, myofunctional therapy, and positive airway pressure.

MOVEMENT DISORDERS IN SLEEP: RESTLESS LEG SYNDROME, PERIODIC LIMB MOVEMENT DISORDER, AND SLEEP-RELATED RHYTHMIC MOVEMENT DISORDER

Restless leg syndrome is a neurologic, sensorimotor disorder characterized by an almost irresistible urge to move the legs. These subjective symptoms of a “need” to move and uncomfortable and unpleasant sensations (**dysesthesias**) occur primarily in the legs, although other body parts (e.g., arms) can also be involved. Some patients with restless leg syndrome, however, do not describe a significant sensory component; instead, they experience the urge to move the legs during periods of

inactivity as the primary or sole presenting symptom. The urge to move and sensory components are usually at least partially relieved by movement, including walking, rocking, shaking, stretching, and rubbing, but typically this works only as long as the movements continue. Symptoms usually begin or are exacerbated by rest or inactivity (e.g., lying in bed to fall asleep or riding in a car for prolonged periods). A unique feature of restless leg syndrome is that the timing of symptoms also appears to have a circadian component, in that they often peak in the evening hours (Simakajornboon, Kheirandish-Gozal, & Gozal, 2009).

Periodic limb movement disorder, in contrast, requires a polysomnographic rather than clinical diagnosis and is characterized by movements that meet specific criteria for a sequence of repetitive, brief (0.5–10 seconds), and highly stereotyped limb jerks. They commonly consist of rhythmic extension of the big toe and dorsiflexion at the ankle. Most individuals are unaware of these movements, but caregivers may describe “kicking” movements during sleep. Associated sleep disruption and/or daytime sequelae (i.e., daytime sleepiness and mood or behavioral changes) must be present to qualify as a “disorder” (Gingras, Gaultney, & Picchietti, 2011).

Sleep-related rhythmic movements include head banging, body rocking, and head rolling. These are all characterized by repetitive, stereotypic, and rhythmic movements/behaviors that involve large muscle groups. These behaviors typically occur during sleep–wake transitions or light sleep stages, and the duration ranges from minutes to several hours (Mindell & Owens, 2015).

Prevalence and Epidemiology

The prevalence rate of restless limb syndrome in children is estimated to be between 1% and 6%. A large telephone survey study (pediatric “REST” study) found a prevalence of “definite” restless leg syndrome in about 2% of children; one quarter to one half had moderate to severe symptoms (Picchietti et al., 2013).

Because the diagnosis of periodic limb movement disorder requires a polysomnogram, the pediatric prevalence rates are more difficult to quantify. In survey studies of periodic limb movement symptoms, rates are between 8% and 12% (Crabtree et al., 2003; Marcus et al., 2014; Mindell & Owens, 2015). In adults, restless limb syndrome and periodic disorder limb movement syndrome co-occur at a rate of 80% (American Academy of Sleep Medicine, 2014).

Studies have suggested that approximately two thirds of infants engage in some type of sleep-related rhythmic movements, body rocking being the most

common. Onset is typically prior to 1 year of age; by 18 months, the prevalence drops to about one third, and by 5 years, it drops to 5% (Mayer, Wilde-Frenz, & Kurella, 2007).

Etiology and Associations with Specific Developmental Disabilities

Overall, it is estimated that 50%–60% of adult restless leg syndrome patients have a positive family history. “Early-onset” restless leg syndrome, also termed “primary” or “familial” restless leg syndrome, appears to have a particularly strong genetic component. It is estimated that 40%–92% of these cases are familial, and the prevalence of restless leg syndrome in first-degree relatives appears to be six to seven times that in the general population (Mindell & Owens, 2015).

A number of studies have implicated low iron levels in both adults and children as an important factor for the presence and severity of both restless leg syndrome symptoms and periodic leg movements (Allen et al., 2018; Dye, Gurbani, & Simakajornboon, 2018).

The postulated underlying mechanisms relate to the role of iron as a cofactor of tyrosine hydroxylase in a rate-limiting step of the synthesis of dopamine. In turn, dopaminergic dysfunction has been implicated as playing a key role in the genesis of both restless leg syndrome and periodic leg movement disorder. Several pediatric case series have suggested that lower-than-normal ferritin levels (defined as less than 50 ng/mL) are found in some 70%–75% of children with restless leg syndrome (Dosman, Witmans, & Zwaigenbaum, 2012).

Medications including antihistamines (such as diphenhydramine/Benadryl), antidepressants (selective serotonin reuptake inhibitors [SSRIs] and tricyclic antidepressants [TCAs]), neuroleptics, and caffeine can all exacerbate underlying restless leg syndrome. Insufficient sleep, as in any underlying sleep disturbance, may exacerbate restless leg syndrome.

Comorbidity between ADHD and restless leg syndrome/periodic limb movement disorder has been commonly reported. For example, it is estimated that over 40% of children with ADHD have restless leg syndrome symptoms and more than a quarter of children with restless leg syndrome have ADHD symptoms (Spruyt & Gozal, 2011). Several studies in referral populations have also found that periodic limb motion occurs in as many as one fourth of children diagnosed with ADHD. Periodic limb motion is also more common in children with sickle cell disease and Williams syndrome.

The etiology of sleep-related rhythmic movements seems to be related to self-soothing behaviors prior to

sleep onset or after night wakings. While often distressing to caregivers and sometimes disruptive to other family members’ sleep, these behaviors are for the most part considered benign and do not result in injury. They usually occur in typically developing children and are thus not indicative of underlying neurological issues. However, in situations that involve children with developmental disorders, such as autism or severe intellectual disability, there may be an increased risk for self-injury due to the frequency and intensity of the behavior, and these children are more likely to also engage in the behavior while awake.

Diagnosis and Clinical Manifestations

Although symptoms of restless leg syndrome may start as early as 6–12 months of age and thus are very difficult to identify, even relatively young children are often able to describe the sensory symptoms. In clinical interviews, children may use colorful descriptors such as “soda bubbling through my veins,” “tiny nails poking my legs,” and “people wrestling in my legs.” They may use terms like squeezing, tingling, wiggling, itching, popping, “funny” feelings, shaking, aching, or pulling and tugging of the legs. The motor symptoms may be observed by caregivers as stretching or rubbing the legs together or increased motor activity in the evening. In querying a child, a useful question is, “If you had to lie perfectly still while you were falling asleep, would you be able to do it?” Although somewhat non-specific, a history of “growing pains” (i.e., recurrent limb discomfort or pain occurring at bedtime and/or during night wakings) is often reported in children with restless leg syndrome and periodic leg movement disorder (Mindell & Owens, 2015).

Difficulties initiating sleep are common in restless leg syndrome, as are reports of restless sleep and twitching or kicking during the night in periodic limb movement disorder. Daytime symptoms may include sleepiness and behavioral complaints. Children with these disorders appear to be at higher risk for mood disorders and decreased quality of life.

Monitoring, Screening, and Evaluation

Screening for symptoms of and risk factors for restless leg syndrome and periodic limb movement disorder is particularly important in children who present with sleep-onset insomnia or unexplained daytime fatigue, a chief complaint of restless sleep, and/or evaluation of ADHD. The physical examination is generally normal (including the neurologic examination) in these children, and, in fact, the presence of abnormal physical

findings (e.g., pain or limitation of extremity movement) suggests an alternative orthopedic, rheumatologic, or neuromuscular diagnosis. As noted above, a nocturnal polysomnogram that includes leg muscle EMG leads is needed to confirm the presence of periodic leg movements but is not required for a diagnosis of restless leg syndrome. As a marker of decreased iron stores, serum ferritin levels in both children and adults with restless leg syndrome are commonly low. Studies have also suggested that low vitamin D and B12 levels may exacerbate symptoms in some cases. No specific diagnostic evaluation is required for sleep-related rhythmic movements, although home videotaping may be quite helpful in confirming the diagnosis.

Treatment, Management, and Interventions

The decision of whether and how to treat restless leg syndrome depends on the level of severity (intensity, frequency, and periodicity) of sensorimotor symptoms, the degree of interference with sleep, and the impact of daytime sequelae. Similarly, the decision to specifically treat periodic limb movements should be based on the presence or absence of nocturnal symptoms (restless or nonrestorative sleep) and daytime sequelae.

The management of restless leg syndrome and periodic leg movement disorder may be summarized by the acronym AIMS: **A**voidance of exacerbating substances, such as caffeine, antihistamines, and specific antidepressants; **I**ron supplementation; **M**uscle therapy (moderate exercise up to a few hours before bedtime, walking, stretching, massaging the affected area, and applying hot or cold packs); and **S**leep hygiene (maintaining consistent bedtimes and wake times, having a bedtime routine, and obtaining adequate nighttime sleep). The recommended dose of supplemental iron is typically in the range of 3 to 6 mg/kg per day for a duration of at least 3 months, followed by increased dietary iron intake once an appropriate ferritin level (at least 50 ng/ml) is reached. Concomitant use of ascorbic acid (vitamin C) appears to improve iron absorption, while iron absorption is reduced when combined with calcium. The absence of iron rich foods in a child's diet may be an important contributor to the finding of low ferritin levels, and a brief discussion of iron rich foods or a referral to a nutritionist may confer some long-term benefits. Pharmacologic agents are rarely necessary to treat these disorders in childhood, but consultation with a pediatric sleep specialist or neurologist is recommended. There are no FDA-approved drugs for treatment of restless leg syndrome in children.

Rhythmic movement disorders can be very disruptive and upsetting to families and typically only

cause superficial physical sequelae. Various behavioral techniques can be effective in reducing the frequency of these behaviors or eliminating them all altogether. These can include an initial focus on eliminating the behavior both during the day and at bedtime, as well as replacement behavioral techniques and charting and rewards. When children with rhythmic movement disorders have a history of trauma, in utero drug exposure, and/or sensory integration problems, a physical therapy intervention may be effective (e.g., brushing, massage, or weight blankets or vests). Generally, no treatment other than reassurance is needed for sleep-related rhythmic movements unless there is evidence of injury. Caregivers should be encouraged to move the crib away from the wall if the noise is disruptive (padding the bed surfaces is usually not effective to stop the behavior). Ensuring sufficient sleep with a regular sleep-wake schedule may help. Making sure the child's bedtime matches his/her fall asleep time may reduce the need to and opportunity for these behaviors at sleep onset. Reducing ambient household noise (e.g., with a white noise machine or fan) may reduce arousals/night wakings. Pharmacologic treatments that have been used in severe cases include clonazepam, hydroxyzine, and tricyclic antidepressants.

Outcomes

No long-term studies have been conducted on the course of restless movement disorder or periodic limb movement disorder in children or adolescents. It appears, however, that restless limb syndrome that begins in childhood or adolescence has a chronic and progressive course and is likely to be a lifelong disorder. Patients with milder disease may have long periods of remission (or episodic exacerbation, as with pregnancy). Cases of secondary restless limb syndrome and periodic limb movement disorder related to iron deficiency generally remit without recurrence when the underlying condition is resolved.

Sleep-related rhythmic movements disappear in 90% of typically developing children by age 4 years. Children who have developmental disorders with sleep-related rhythmic movements associated with self-injurious behaviors often need more intensive management and follow-up.

Talking Points

1. Restless leg syndrome is a neurological disorder characterized by an irresistible urge to move the legs. It is often accompanied by leg discomfort and is a comorbidity in children with ADHD.

2. Treatment of restless leg syndrome includes avoiding exacerbating substances (such as caffeine and SSRIs), iron supplementation if appropriate, muscle therapy, and good sleep hygiene.
3. Rhythmic movement disorders, including head banging and body rocking, are self-soothing behaviors that occur prior to sleep onset and after night wakings. Although distressing to parents, these behaviors are considered benign and are typically not indicative of underlying neurological issues.

SUMMARY

- Sleep disorders in children with developmental disabilities are extremely common.
- Common presenting complaints such as difficulty initiating or maintaining sleep may be due to a variety of biologically and behaviorally based causes (e.g., behavioral insomnia, restless leg syndrome, and circadian-based phase delay or OSA).
- Practitioners should have a regular systematic approach to screening for sleep problems in these children. Comorbid sleep disorders may further compromise daytime function in children with NDD, including mood and behavioral regulation, attention, and cognition. Conversely, successful treatment may improve functioning in both patients and families.
- Behavioral interventions used to treat insomnia in typically developing children can also be effective strategies in children with NDD.
- Essential questions for identifying sleep problems include snoring, difficulty initiating or maintaining sleep, difficulty waking in the morning, and unplanned episodes of sleep during the day.

CHAPTER 29

Feeding and Its Disorders

Peggy S. Eicher

Upon completion of this chapter, the reader will

- Describe the feeding and swallowing process and how it changes as an infant grows and develops
- Define how medical, motor, and interactional problems influence a child's feeding function
- Recognize some of the common feeding problems that occur in children with neuro-developmental challenges and what factors contribute to them
- Identify the basic components of a treatment approach to feeding problems

Feeding a child is one of the most satisfying experiences a caregiver can have. However, when it isn't successful, it can be one of the most frustrating. Feeding problems are very common for children both with and without neuro-developmental challenges. Estimates vary from 25%–50% of typically developing children and up to 80% of children with neuro-developmental challenges will present with a feeding concern (Lukens & Silverman, 2014). Therefore, it is paramount that pediatric care providers are equipped with a working knowledge of the normal feeding process and how medical, motor, and behavioral factors influence it. This will enable them to identify what is contributing to the development and maintenance of the child's feeding problem and thereby most effectively treat it. This chapter first reviews the normal feeding process and the changes that occur during typical growth and development. It then describes the most common feeding problems and how various medical and developmental

conditions influence the feeding process to contribute to the development of those feeding problems. Treatment approaches and anticipatory guidance to prevent development of feeding problems will be discussed as well. The challenge in treating feeding problems in children with neuro-developmental challenges is not only the issue of identifying all of the factors interfering with the child's feeding function, but also of understanding how they interrelate.

■ ■ ■ CASE STUDY

Harry is an 18-month-old boy who was referred for a feeding evaluation because he “can't advance past purées and doesn't chew.” He was delivered by C-section at 36 weeks' gestation, weighing 7 pounds. He had mild hyperbilirubinemia for which he received a few days of phototherapy, but he transitioned well in the full-term nursery and was discharged home with his mother. Harry

crawled at 12 months and walked at 18 months. He can repeat a few words but does not use them spontaneously. He receives therapies through the early intervention program for his delay in motor and expressive language.

Harry breast-fed for 5 weeks and spit up a lot. With introduction of bottle feeding at 5 weeks, he refused to breast-feed. He transitioned to a predigested formula, although he continued to spit up frequently. His mother tried to introduce spoon feedings at 6 months of age. He gagged and vomited on these no matter what the baby food. She tried crunchy chewables, which he would self-feed but then vomit. He was able to tolerate puréed soup like table food purées at 9 months. By 14 months, he was able to ingest stage 2 baby food but could not tolerate stage 3. He continues to drink milk, but only from a bottle and always while lying down. He will drink water from a soft straw cup. Meals are difficult; he always needs distraction, and it takes over an hour to feed him 6 ounces. His parents find that they have to increase distractions as the meal progresses. Sometimes, his mother will resort to sitting him on the floor and feeding him a pouch of baby food by squeezing the contents into his mouth while he sucks on the spout of the pouch. Harry gags at the sight of other people's food. The easiest meal to feed him is in the middle of the day. He wakes up several times a night crying. Harry passes stools one to three times a day, usually after a bottle and with straining. The stool is typically a playdough-like consistency, with occasional hard pellets. He underwent a gastroesophageal endoscopy and modified barium swallow 3 months ago because of his mother's concerns that he is not chewing. The results of both tests were totally normal.

On evaluation, Harry's weight and length were at the 95th percentile for his age. Oral structures were intact. Lungs were clear to auscultation, with no areas of rhonchi or wheezing. His abdomen was distended, but soft with palpable stool in the left lower quadrant. His muscle tone was in the low normal range throughout. Harry's sitting posture included a posterior pelvic tilt, decreased thoracic extension, bilateral shoulder protraction, and forward head posture. Standing posture included decreased abdominal activation with a mild increase in lumbar lordosis. Harry ambulates as his primary means of mobility with fair coordination but with a wide base of support and arms elevated. He uses decreased trunk rotation and decreased abdominal activation, resulting in his weight being set anterior. Passive range-of-motion limitations were noted in bilateral trunk rotation and trunk extension. Decreased balance and abdominal activation were noted with all gross motor activities, and he had a posterior loss of balance.

During the feeding observation, Harry sat in a high chair without the straps on. In the beginning of the meal, he leaned over the tray to look at and swipe on the iPad

that was being used to distract him. As the meal progressed his hips slid farther forward in the chair. His mother spoon-fed him puréed food. Harry's acceptance was poor despite the distraction with the iPad. He continually batted at the spoon with his left hand. When he accepted the spoon, he opened his mouth partially and his tongue was retracted. Only the tip to quarter of the toddler spoon entered his mouth, and he closed his lips to strip the spoon, compressed, and swallowed, moving his tongue minimally. He did not lick his lips. At rest, Harry occasionally rolled his tongue around in his mouth. His swallow appeared intact.

Harry needs intervention for his feeding problem. He does not move his tongue as a means of oral transport, and so advancing texture is not possible. Furthermore, his resistance to opening his mouth prevents his mother from stimulating his tongue with the spoon. Meals are so difficult that only his mother and babysitter can feed him; he will not be able to attend preschool unless this improves. Effective intervention must identify what factors are preventing him from eating more successfully. However, identifying those factors correctly requires familiarity with the normal feeding process and how it changes over the first few years of life.

Thought Questions:

Choose a condition of interest—such as autism spectrum disorder or cerebral palsy—and make note of the medical, developmental, and psychosocial factors that can contribute to the development of feeding disorders. For that condition, how can the different members of the interdisciplinary care team contribute to treatment?

THE FEEDING PROCESS

Swallowing

Swallowing is one of the most complex motor activities that humans perform. It entails the coordinated function of striated and smooth muscles of the head and neck plus the respiratory and gastrointestinal (GI) tracts. Swallowing also requires input from the central, peripheral, and autonomic nervous systems (Erasmus, van Hulst, Rotteveel, Willemsen, & Jongerius, 2012; Leopold & Daniels, 2010; Miller, 1986). Swallowing can be divided into four phases (Figure 29.1). Typically, after the first 4–6 months of life, the oral preparatory (Phase 1) and oral transport (Phase 2) phases become primarily volitional. During these oral phases, food is broken up and formed into a bolus by the tongue; the tongue then transports the bolus to the back of the throat. The pharyngeal transfer phase (Phase 3) begins when the bolus passes the faucial arches (near

Figure 29.1. A) Phase 1, Oral Preparatory: Food is taken into the mouth, processed to a manageable consistency, and then collected into a small parcel, or bolus. B) Phase 2, Oral Transport: The bolus is then pushed backward by the tongue toward the pharynx. C) Phase 3, Pharyngeal Transfer: As swallowing begins, the epiglottis normally folds over the opening of the trachea to direct food down the esophagus and not into the lungs. D) Phase 4, Esophageal Transport: The peristaltic wave moves the bolus down the esophagus toward the stomach.

the tonsils) and triggers the start of the swallowing cascade. This involves the involuntary sequence of highly coordinated movements of the pharyngeal (throat) and esophageal (tube-to-stomach) muscles. With each swallow, respiration ceases as the soft palate elevates to close off the nasopharynx (entrance to the nasal airway at the back of the mouth). At the same time, forward movement and elevation of the hyoid bone results in 1) tipping of the epiglottis (a projecting piece of cartilage) to cover the trachea (entrance to the lungs) so that food does not slip into the airway and 2) opening the upper esophageal sphincter (UES; the entrance to the esophagus). A wave-like motion (peristalsis) originating in the back wall of the throat propels the bolus past the closed airway, through the open UES, and into the esophagus, marking the start of the esophageal transport phase (Phase 4). During this phase, the bolus is pushed down the esophagus by continuation of the peristaltic wave, which signals the relaxation, or opening, of the lower esophageal sphincter (LES; the entrance to the stomach), allowing the bolus to pass into the stomach. Entrance of the bolus into the stomach and the subsequent closure of the LES mark the end of the esophageal transport

phase. These motor movements are synchronized and transmitted through the motor output side of the swallowing center in the brainstem. Sensory information from each level feeds back to the swallowing center to determine whether swallowing should stop, slow down, or continue (Erasmus et al., 2012; Lau, 2016).

The Influence of Growth and Development on the Feeding Process

Developmental Changes in Oral-Motor Skills

The process of swallowing evolves as the nervous system matures and the child experiences successful practice. The oral preparatory phase of swallowing is most influenced by growth and development. Reflexive oral-motor patterns in the infant are integrated into more complex oral-motor patterns that are learned through practice (Sheppard, 2008). Cortical maturation enables more independent and finely graded tongue and jaw movements to develop under increasing volitional control (Leopold & Daniels, 2010). Acquisition of oral-motor skills occurs in a sequential, stepwise

progression. Mastery of skills at each level provides the foundation for skills at the next level. Thus, no stage can be skipped without interfering with the foundational skills needed for the next stage (Sheppard, 2008).

Suckling Suckling is the earliest oral pattern. Suckling motions and swallowing activity have been reported in fetuses by 15 weeks' gestation (Nowlan, 2015). Suckling and swallowing are gradually coupled over the course of gestation; the fetus in utero can swallow half an ounce at 20 weeks' gestation and up to 15 ounces each day at 38–40 weeks' gestation. Only following birth and with some practice, however, does the infant develop the rhythmical suck-swallow bursts coordinated with breathing to allow functional feeding. Mature suckling, in which the tongue moves in and out while riding up and down with the jaw, creating a wave-like motion, consists of two components: suction and expression (Lau, 2016). Suction refers to the intra-oral negative pressure that pulls liquid into the mouth. Expression corresponds to the compression and/or stripping of the tongue against the hard palate to eject liquid into the mouth. Studies of nutritive sucking in preterm infants have revealed that suckling develops in stages, from the most immature with absent suction and only arrhythmic expression to the most mature with rhythmic bursts of alternating suction/expression (Lau, 2016). They have also identified that the expression component matures before the suction component (Lau, 2016). Infants with an immature suck having only the expression component can be successful with bottle feeding as expression can compress the nipple lying in their mouth. However, breast feeding would be much more difficult because the suction component of suckling enables the infant to latch onto the breast and keep the nipple in the mouth (Lau, 2016).

With further maturation and practice, the tongue exerts increasing force to propel a bolus of food posteriorly to initiate the swallow reflex, and the rate of swallowing increases. Underlying this increased swallowing rate are the maturational changes occurring in three elements of the esophageal phase. First, a well-developed UES and esophageal motility appear around 33–34 weeks' postmenstrual age to enable increased coordination between pharyngeal bolus propulsion and relaxation of the UES and timely transport of the bolus from the pharynx into the esophagus. With maturation of the esophageal body, anterograde peristaltic waves increase and the frequency of nonperistaltic waves decreases (Lau, 2016). The LES functions as a one-way valve to prevent the backward flow or reflux of food up into the esophagus (termed gastroesophageal

reflux [GER]; Figure 29.2). The LES controls bolus movement into the stomach and reflux of stomach contents back into the esophagus. Typically, the LES continues to mature over the first 3 months of life with elongation of the esophageal body beneath the diaphragm, allowing development of a mature pressure gradient (Rybak, Pesce, Thapar, & Borrelli, 2017).

For the first 3–4 months of life, suckling is a reflexively driven activity that occurs involuntarily whenever something enters the infant's mouth. With brain maturation, the reflex is integrated and the infant can control initiation of the suckle pattern. Likewise, the ability to stabilize the jaw increases and the tongue dissociates from the jaw, leading to the next stage of sucking.

Sucking During sucking, the lips purse, the jaw opening is smaller and more controlled than in suckling, and the tongue is raised and lowered independently of the jaw. When sucking replaces the anterior/posterior pattern of suckling, usually around 5 months of age, the child can progress to spoon feeding. Because of the predominant up-and-down pattern of sucking, food can be transported to the back of the mouth without first riding out of the mouth on the tongue.

Figure 29.2. Food passes down the esophagus (A), through the lower esophageal sphincter (D), and into the stomach (E) and duodenum (F). If the sphincter does not remain closed after the passage of food, reflux (C) occurs, as shown in this barium study in a child with a nasogastric tube (B) in place.

Munching and Chewing With munching, small pieces of food are broken off, flattened, and then collected for swallowing. Munching consists of a rhythmic bite-and-release pattern with a series of well-graded jaw openings and closings. More important, however, is the emergence of tongue lateralization, which enables the child to move food from side to side and then to regather it in the midline. Actual chewing and grinding food into smaller pieces does not occur until the child acquires a rotary component jaw movement, a capacity that emerges around 9 months of age and is gradually modified via repetition until, by around 2 years of age, it approximates the adult pattern (Gisel, 2008).

Integration with Growth of Oral Structures

Typically, the attainment of new oral-motor skills coincides with the change in oral structures that occurs with growth. The infant, for example, is perfectly equipped for nipple feeding. The cheek fat pads confine the oral cavity while the tongue, soft palate, and epiglottis fill much of the mouth, easing the formation of the vacuum necessary to draw fluids out of the nipple. The larynx (voice box at the entryway to the lungs) is almost tucked under the tongue, necessitating less controlled transport to guide the liquid past the airway and into the esophagus (Bosma, 1986).

With growth, the jaw and palate enlarge in relation to the soft tissue structures, allowing room for the teeth (Figure 29.3). The larger oral cavity is not as

efficient for nipple feeding but facilitates spoon entry and lateralization. The larynx descends and moves backward as the neck lengthens. This elongation necessitates increased postural control of the head and neck to enable safe swallowing. Meanwhile, the changes occurring in the child's oral-motor pattern afford the tongue increasing control of collection and propulsion of the food in the mouth and pharynx, enhancing the child's ability to guide the food safely past the airway.

Integration with Psychomotor Development

The ontogeny in oral-motor skills typically corresponds with progression in other areas of development (Table 29.1). The sucking pattern emerges as the child develops gross motor control for righting the head and sitting independently. Munching skills with tongue lateralization typically occurs contemporaneously with a pincer grasp for picking up small pieces, eruption of teeth, and increased trunk control enabling crawling. Desire for inclusion in parents' meals and independence set the stage for introduction of table food pieces and self-feeding (Sheppard, 2008). Interestingly, food neophobia, or the normal "picky" stage that commonly occurs between 1–2 years, is thought to be evolutionarily associated with the gross motor skill of walking as a protective mechanism against the child eating dangerous substances they encounter while mobile (Aldridge, Dovey, Martin, & Meyer, 2010).

Figure 29.3. The mandible (jaw) enlarges, enabling room for teeth and a larger oral cavity. The larynx descends and moves posteriorly, necessitating increased control of bolus propulsion to guide it past the airway.

Table 29.1. Coordination of developmental milestones with feeding skills

Age	Gross motor	Fine motor	Oral motor	Feeding
Birth–4 months	Increasing head control Push up in prone	Brings hands together at 3 months	Suckle pattern	Nipple feeding
4–7 months	Derotational righting- rolling Sits independently	Reaching Hand to mouth play	Sucking pattern Jaw stability Phasic bite	Initiation of spoon feeds Tongue used to move food back rather than with suction
8–10 months	Lateral props Moves in and out of positions Crawling	Hand raking movements Palmar grasp Pincer grasp	Lateral movement of tongue Crushing jaw movements	Crunchy chewables Moving piece laterally with finger Self-feeding small pieces
10–12 months	Pulls to stand Crawls for mobility	Mature pincer grasp Voluntary release	Controls position of food in mouth with tongue Cup drinking	Soft chewables introduced Holds spoon
12–18 months	Walking	Uses utensils	Rotary chewing	Brings spoon to mouth Increased chewables in meals
18–24 months	Runs	Increasing utensil use Dips food in sauce	Increasing strength and endurance of rotary chew	More self-feeding Avoids new foods

Interaction with Feeder Because children are dependent on a caregiver for nutrition, the quality of the mealtime interaction with the feeder is tremendously important. Starting with nipple feeding, whether breast or bottle, the American Academy of Pediatrics (n.d.) strongly recommends “responsive feeding” rather than feeding on a schedule. With responsive feeding, infants are fed when they exhibit hunger cues and are allowed to stop feeding when they exhibit signs of being full and satiated. This leads the infant to learn to interpret feelings of hunger and satiety, which enables them to better develop the ability to self-regulate food intake. As the infant grows, the feeder should continue to be sensitive to the infant’s cues of hunger and satiety, while establishing a mealtime routine that maximizes the infant’s comfort and enables the successful practicing of emerging skills. This approach contributes to making feeding time a pleasant interaction.

Many feeding transitions occur in the first 3 years of life, and a child with a neuro-developmental challenge may have more difficulty during these periods in adjusting to changes in textures, utensils, and settings. This heightens the importance of a stable mealtime environment, interactive communication, and consistent interactions between the caregiver and child. Consistency imparts a sense of familiarity that enables children to be comfortable and more tolerant of mealtimes.

Feeding Problems

Feeding problems are very common in childhood. Children are considered to have feeding difficulties if they are unable or unwilling to eat a similar volume or variety of foods as their peers (Marshall, Hill, Ware, Ziviani, & Dodrill, 2016). The type of feeding problem varies by how much the child eats, what they eat, when they eat, how they eat, and what the caregiver thinks they should be eating. Common feeding issues surround advancing texture, picky eating or food selectivity, food refusal, limited intake, and challenging mealtime behaviors. Because younger children are dependent on a caregiver at mealtimes, the interaction between child and feeder influences whether the child’s mealtime function is perceived as a problem or not (Aldridge et al., 2010; Kerzner et al., 2015).

A feeding problem is considered a feeding disorder if the problem exists more than 1 month and/or results in 1) significant weight loss or nutritional deficiency, 2) dependence on tube feeding or nutritional supplements, or 3) impairment in psychosocial functioning and developmental deviation or delay (Phalen, 2013).

Unfortunately, there is not one agreed upon classification system that captures the complexity of the multiple influences on feeding that can contribute to the development of a feeding disorder. Historically, feeding problems were associated with poor growth and

classified as organic, with underlying medical issues, or nonorganic, with no physiological cause for the poor growth (Marshall et al., 2016). As there is increased recognition of the many factors influencing pediatric feeding, the field has moved toward a conceptualization of feeding difficulties that recognizes the effects of both biological and behavioral factors and their mutual interaction (Crist & Napier-Phillips, 2001). In 2013, the term **avoidant/restrictive food intake disorder (ARFID)** was introduced in the *Diagnostic and Statistical Manual, Fifth Edition* (American Psychiatric Association, 2013), in an attempt to provide an improved classification for feeding disorders (Phalen, 2013). ARFID entails an intake disturbance in which a child eats too little, eats a limited variety, or has fear of eating, resulting in either faltering growth, nutritional deficiency, dependence on nutritional supplements either orally or by tube, and/or interference with psychosocial functioning. If the feeding disorder is associated with an underlying condition, the presentation of the feeding disorder is more severe than would be expected (Kreipe & Palomake, 2012). Kerzner and colleagues (2015) argue that because of the interaction of the child and feeder and the influence of the feeder's perception of what the child should be eating, a classification scheme must also take into account the feeder's style.

PREVALENCE AND EPIDEMIOLOGY

Feeding and eating problems affect 25%–40% of healthy, typically developing infants and young children; 40%–70% of children with chronic medical conditions; and up to 80% of children with neuro-developmental disabilities (Lukens & Silverman 2014). The lack of an agreed upon classification scheme has made it difficult to have accurate prevalence estimates. Although “picky” eating can be a normal “phase” before 2 years, it becomes a common problem in children ages 3–11 years, with 13%–22% being reported as food selective (Chatoor, 2002). Up to 40% of these children will continue to be selective into adolescence (Mascola, Bryson, & Agras, 2010). In fact, it is estimated that persistent restriction in food consumption, whether volume or variety, affects up to 5% of children, making it one of the most frequent concerns in pediatrics (Sharp et al., 2016). Epidemiologic studies performed in the United States report that 13%–29% of children and adolescents fit the criteria for avoidant/restrictive food intake disorder (see section on Avoidant/Restrictive Food Intake Disorder) upon initial presentation to eating disorder services. Feeding difficulties, most often food selectivity, are reported to occur in 46%–89% of children on the autism spectrum (Marshall et al., 2016). Children

born prematurely, small for gestational age, or with congenital malformations also have an increased risk of feeding disorders, particularly oral-motor problems (Johnson et al., 2016). One study reported that feeding problems occur in 30% of infants born prematurely (Rybak, 2015).

ETIOLOGY AND ASSOCIATIONS WITH SPECIFIC DEVELOPMENTAL DISABILITIES

Feeding problems result from a combination of several factors: anatomical abnormality, motor or sensory dysfunction, medical or psychological conditions, growth abnormality, learning difficulties, and social interaction difficulties (Berlin, Lobato, Pinkos, Cerezo, & LeLeiko, 2011). Because children learn how to eat through practice, anything that impedes successful practice can result in a feeding problem (Sheppard, 2008), and because children with neurodevelopmental challenges have a higher frequency of medical, motor, and learning problems, their risk for feeding problems is greater.

Multiple medical and developmental factors are frequently present in children with feeding problems. Reportedly 48%–85% of children with feeding problems have two or more conditions, and 86%–100% have at least one problem in addition to their feeding difficulties (Berlin et al., 2011). These underlying conditions increase the overall risk of a feeding problem in general rather than for any specific type of feeding problem. Harry, for example, was born preterm, has symptoms consistent with GER, and has developmental delay.

The Influence of Medical Conditions on Feeding

Oral-motor problems in children may have a number of causes, including 1) an anatomical abnormality such as a cleft palate; 2) abnormalities in muscle tone; 3) compensatory postural and breathing patterns resulting from various medical issues, especially respiratory and GI problems; and 4) limited practice of more mature oral-motor patterns. The integration of growth with enlarging structures and increasing neurologic control over posture and oral-motor pattern is so important that delay in gross motor or oral-motor development can decrease feeding efficiency and foster swallowing incompetency (Sheppard, 2008).

Conditions Affecting the Upper Aerodigestive Tract Feeding difficulties may be the first sign of an anatomical defect involving the oral or nasal cavities,

pharynx, or esophagus that can adversely affect swallowing. Clefts, such as those in the lip or palate, interfere with sealing off the oral cavity, decreasing the child's efficiency at generating negative pressure and collecting the food in preparation for swallowing. A change in size or shape of an oral structure that affects coordination of the swallowing process can also be a significant problem; for example, enlarged tonsils and adenoids may render the child dependent on his or her mouth as an airway, influencing suck-swallow-breath timing and even coordination if the flow of the food bolus is disrupted by the tonsils. Normal esophageal peristalsis (the involuntary constriction and relaxation of the muscles of the esophagus and intestine, creating wavelike movements that push food forward) is interrupted in children with esophageal atresia or tracheoesophageal fistulae, which are abnormal connections of the esophagus to the respiratory tract. Even after repair of these abnormal connections, the child's swallow will be influenced by the degree of abnormal peristalsis remaining in the esophageal phase of the swallow.

Successful feeding is dependent not only on the anatomy and function of the oral and pharyngeal structures involved in swallowing, but also on the child's medical status, especially with regard to respiration and digestion (Lau, 2016). Sensory information from the lungs, heart, and GI tract goes directly to the swallowing center in the brain. Through this input, a child with breathing difficulty (e.g., wheezing) may start to drool because swallowing frequency slows as a result of the need for increased respiratory rate (Gewolb & Vice, 2006; Khoshoo & Edell, 1999). Current research suggests that the feeding difficulties of preterm infants may relate more to inappropriate swallow-respiration interaction than to the suck-swallow interaction (Fucile, McFarland, Gisel, & Lau, 2012).

Feedback from the GI Tract

Irritation Input from the GI tract (one long tube that runs from the mouth to the anus) also has a significant impact on the feeding process (Figure 29.4). Chaidez, Hansen, and Hertz-Picciotto (2014) reported that children on the autism spectrum or with other neurodevelopmental challenges are at least three times more likely to experience GI symptoms than typically developing children. Children with feeding problems have high rates of GI problems no matter what other comorbid factors are present (Berlin et al., 2011). Gastroesophageal reflux (GER) is the backward flow of stomach contents up the esophagus. GER can result in vomiting, and if the stomach's contents enter the airway, the reflux can cause coughing, wheezing, and even pneumonia (Rybak

Figure 29.4. After food enters the stomach, it is mixed with acid and is partially digested. Then it passes through the three segments of the small intestine (duodenum, jejunum, and ileum). There, digestive juices are added and nutrients are removed. The remaining water and electrolytes pass through the colon, where water is removed. Voluntary stooling is controlled by the rectal sphincter muscles.

et al., 2017). In addition, repeated entry of stomach acid into the esophagus can cause inflammation (esophagitis) that makes eating painful. The child may respond to GER by vomiting, refusing to eat, or taking frequent breaks while eating. GER can result from a number of abnormalities, and some forms can be inherited (Hu et al., 2004). The most common mechanism for GER is transient relaxation of the LES, which occurs with the arrival of the propelled bolus down the esophagus or with increased intragastric pressure, as with burping or stomach distention. Lowered LES resting tone from a head injury or hiatal hernia can also allow reflux of gastric contents (Rybak et al., 2017). LES function can be influenced by meal volume and composition (Kim et al., 2013), and reflux also can result from increased abdominal pressure caused by straining or constipation (Borowitz & Sutphen, 2004).

A child with GER who feels uncomfortable all the time may lose interest in eating or may accept only a few favorite foods (Chaidez et al., 2014). GER can also affect the movement of the tongue, throat, and esophagus, causing the child to choose foods that need less oral preparation and are therefore easier to swallow. The resulting lack of practice with more difficult textures can lead to delayed oral-motor development.

Harry, the child from the opening case study, exemplifies the myriad ways GER can interfere with feeding. Although frequent emesis occurs commonly

in the first few months of life, Harry's continued emesis despite transition to a predigested formula that empties faster is consistent with ongoing GER. Other symptoms consistent with GER included gagging at the sight of his parent's food and waking up several times a night. GER explains his difficulty with spoon feedings, in that his ongoing tongue retraction prevents him from using his tongue as a transport surface to propel the food posteriorly. His oral defensiveness prevents his mother from getting the spoon into his mouth to stimulate a more appropriate oral pattern. Thus, the only pattern he practices is nipple compression, which does not enable him to manipulate crunchy chewables, lumps, or even thicker purées. However, he can be successful sucking from the pouches because his mother squeezes the contents into his mouth. He then uses his cheeks and lips to generate enough suction to move the thin purée contents posteriorly.

Vomiting, feeding problems, poor weight gain, and irritability are also characteristics of adverse food reactions, including food allergy and food intolerance. The prevalence of food allergy has been reported as affecting up to 18% of children (Rybak et al., 2017). The most common allergenic foods are cow's milk, hen's eggs, soy, wheat, fish, peanuts, and shellfish (Rybak et al., 2017). Eosinophilic gastroenteropathies are a heterogeneous group of non-IgE-mediated food allergies characterized by feeding intolerance and GER symptoms. Biopsies taken from the lining of the involved area of the GI tract demonstrate increased accumulation of eosinophils, the allergy-reactive white blood cells (Simon, Straumann, Schoepfe, & Simon, 2017). The affected children also frequently have food sensitivity, shown through skin testing, as well as clinical evidence of other allergic disease (Simon et al., 2017). Recent studies support early introduction of some highly allergenic foods to actually help decrease development of food allergies (Ierodiakonou et al., 2016; Perkin et al., 2016; Togias et al., 2017).

Another form of food intolerance is lactose intolerance. Approximately 70% of the world's population has an inherited deficiency of the enzyme lactase, which normally breaks down milk sugar (lactose) to allow its absorption (Vandenplas, 2015). With lactase deficiency, unabsorbed lactose irritates the intestinal wall and causes abdominal discomfort, vomiting, and diarrhea after ingesting milk products. Yet, dairy products are an important, if not the main, source of calcium, vitamin D, and protein for many, rendering their potential elimination challenging. Symptoms of lactose-caused GI irritation can be minimized by staggering milk intake throughout the day, taking lactase pills before ingesting a milk product, or using lactase-containing or lactose-free dairy products.

Dysmotility The phenomenon of "dumping" occurs when the stomach empties too rapidly. Symptoms of dumping include nausea, vomiting, diarrhea, heart palpitations, and weakness (Calabria, Charles, Givler, & De Leon, 2016). Children receiving carbohydrate-based, high-calorie supplements or formulas can have symptoms of dumping, and children who have had a surgical procedure to weaken the pylorus are particularly at risk. Avoidance of dumping requires slowing the rate of stomach emptying or decreasing the concentration of food delivered to the duodenum. This can be accomplished by 1) slowing the feeding rate using continuous feeding, 2) using fat-based instead of carbohydrate-based caloric supplements, or 3) changing to a formula with a lower caloric concentration (Garipey & Mousa, 2009).

Nausea, vomiting, and bloating may signal delayed stomach emptying (Jericho, Adams, Zhang, Rychlik, & Saps, 2014). Normally, stomach wall contractions mix and push the stomach contents into the duodenum, the upper part of the small intestine. Delayed stomach emptying can be caused by abnormal stomach contractions, a blockage in the pylorus (the sphincter at the junction of the stomach and the duodenum), poor intestinal motility, or a meal heavy in fat or protein.

Digested nutrients get absorbed through the jejunum and ileum (the middle and lower portions of the small intestine), whereas nonabsorbable nutrients, called bulk or fiber, pass to the large intestine, or colon. Although movement from the stomach to the end of the ileum may take only 30–90 minutes, passage through the colon may require 1–7 days. Rapid movement through the colon leads to diarrhea, whereas slower movement causes more water to be absorbed, resulting in hard stools and constipation. Proper bowel evacuation requires adequate fluid, fiber, and coordinated propulsive muscle activity (Dehghani et al., 2015). Overly loose stools may be caused by 1) lactase deficiency, 2) inadequate dietary fiber, 3) dumping, 4) overaggressive use of laxatives or enemas, 5) passage of loose stool around an impaction, 6) disruption in the balance of gut flora, or 7) dietary imbalance via overingestion of fruit juices.

Constipation and/or diarrhea are common problems for children with neurodevelopmental challenges. As an example, almost half of children on the autism spectrum may have either constipation or diarrhea (Holingue, Newill, Lee, Pasricha, & Daniele Fallin, 2017). Chaidez and colleagues (2014) have reported that children with ASD are six times more likely to report diarrhea or constipation than typically developing children. Children with other developmental disabilities are five times more likely than their peers to report constipation (defined as hard stools or a delay

or difficulty in defecation that is present for 2 or more weeks; Buie et al., 2010). In addition to aggravating the risk of reflux by increasing intra-abdominal pressure, constipation can be associated with cramping and discomfort that interferes with appetite and contributes to early satiety, sensitivity to foods, and/or swallowing difficulty (Buie et al., 2010; Chaidez et al., 2014). There is some evidence to indicate a direct relationship between reduction of stool in the rectum and decreased abdominal pain with increased appetite, suggesting a communication between rectal fullness and rate of gastric emptying (Boccia et al., 2008). In the case study, Harry has mild constipation in that his stools are hard pellets and come after he drinks a bottle, which in turn may be exacerbating his GER.

Influence of Other Medical Conditions Any medical condition that impairs the function of the respiratory tract or GI tract can influence the feeding and swallowing process. For example, chronic diseases, including asthma, kidney disease, and inborn errors of metabolism (see Chapters 16 and 24), can contribute to the development of a feeding problem. Moreover, these disorders can influence one another. For example, an increase in the effort to breathe can influence GI function by changing the pressure relationship between the chest and abdomen (Ayazi et al., 2011). During an asthma attack, the child generates increased negative lung pressure to breathe; therefore, abdominal pressure is increased relative to chest pressure, increasing the probability of GER. Likewise, GER can contribute to reactive airway narrowing, wheezing, and increased effort to breathe (Jung et al., 2012; Kostovski & Zdraveska, 2015). Thus, a vicious cycle can start fairly easily. Unfortunately, if oral feeding is interrupted for prolonged periods of time for any reason, the child may need to restart feeding at an easier texture, especially if the child has cerebral palsy.

The Interaction of Medical, Sensorimotor, and Psychomotor Conditions

The sensory and motor systems provide both the structural foundation and the sensory information that enable a child to practice and master oral-motor skills. Because the feeding process involves internal activities such as breathing, digestion, and elimination, structural alignment, control, and sensory input affect the feeding process and are in turn affected by it. Abnormal muscle tone, whether high or low, and/or persistent primitive reflex activity (as seen in cerebral palsy; see Chapter 21) interfere with trunk support as well as the appropriate trunk, neck, and head alignment necessary

for successful feeding. Likewise, medical conditions can significantly influence posture and alignment. GI discomfort, whether from irritation (as with esophagitis) or distension (as with constipation), compels the child into postures that lessen abdominal pressure. Respiratory conditions that increase the child's effort to breathe lead the child to assume postures that increase the size of the airway. These tend to be extensor positions that interfere with control and alignment through the hips, back, head, and neck. Lack of adequate trunk support and improper alignment greatly hinder rib cage expansion, which ultimately interferes with respiration and increases pressure on the stomach and abdominal cavity. Due to inadequate support and restricted respiration, the shoulders typically elevate, reducing the stability of the base of support for the head and neck. Improper head and neck alignment makes guiding a bolus past the airway more difficult, increasing the risk of aspirating food into the lungs (Alghadir, Zafar, Al-Eisa, & Iqbal, 2017; Larnert & Ekberg, 1995). Improper alignment also limits tongue movement and interferes with oral-motor patterns (Figures 29.5).

For all of these reasons, a child should be seated during feedings with a firm base of support to control positioning of the hips and provided with adequate trunk support to allow neutral positioning of the head and neck. Moreover, the ears and shoulders should be aligned in the same vertical plane as the hips. This may require a slightly reclined position if the child cannot yet sit independently. Some children, in fact, prefer to drink while lying down. Such reclining, if the child has GI problems, may start as a way to stretch out and decrease the pressure on the abdomen or to support the rib cage to facilitate breathing. However, the child then may become dependent on gravity rather than on active tongue transport to move the bolus. As a result, spoon feeding or drinking in an upright position, which requires active oral transport, is not successful.

Harry always lies down to drink his bottle, decreasing his experience using his tongue as the controlling transport surface. Although his mother usually feeds him in a highchair, Harry leans over the tray in the highchair so his head is in a head forward position, which retracts his tongue at rest, making it impossible for his mother to stimulate his tongue with the spoon. Tongue retraction makes it even harder for him to manipulate the food bolus, contributing to his resistance.

Frequently children will avoid certain sensory experiences that cause them discomfort because a sensation is associated with past or current painful, negative stimuli. In regard to feeding, this may involve refusing certain textures, avoiding oral stimulation, or even

Figure 29.5. A) The child is in a neutral head position with a slight chin tuck. The neutral position allows for open airway while allowing the epiglottis to fall away from the tongue base, opening the vallecular space. This position gives the tongue a strong base of support off of which to move effectively with increased range and control. Widening the vallecular space acts as a “safety net” to catch any early leak of the food bolus from the oral cavity before the swallow. B) The child is in a position of head and neck extension. With neck extension, the tongue base retracts, apposing the epiglottis and eliminating the vallecular space. Tongue retraction decreases control of posterior tongue transport. Moreover, by minimizing the vallecular space, this position decreases the possibility of the vallecular “safety net.”

hypersensitivity to the smells or visualization of non-preferred foods. This hypersensitivity may result from an abnormal response of the child’s sensory system, but it can be seen also as part of the sensory feedback from a medical condition. For example, a child with GI discomfort may refuse new textures or feel nauseated and anxious at the sight of a spoon or even in response to the smells of other’s food, as in Harry’s case. In fact, GER can contribute to aspiration by desensitizing the larynx and weakening the laryngeal protective responses (Jadcherla, Hogan, & Shaker, 2010). With treatment of the medical condition, the sensory problems can resolve. A feeding problem may also develop if a medical or developmental condition chronically prevents the child from ingesting an appropriate amount without stress. The child then starts to associate discomfort and pain with feeding and learns to avoid feeding situations. This food avoidance or aversion can continue even after the medical condition has resolved, especially in children who have difficulty interpreting or integrating sensory input from elsewhere in the body.

The child’s fine motor and adaptive skills influence the choice of utensils and level of independence at mealtime, and cognitive abilities help to shape how the child interacts with the mealtime environment. Because children are dependent on their caregivers for feeding, and thus for nutrition, effective caregiver–child communication during mealtime is crucial, and an understanding of the child’s cognitive level and sensitivity to nonverbal cues prepare the caregiver to

effectively communicate with the child. The absence of effective communication increases the likelihood of maladaptive behaviors at mealtime, such as expelling, refusal, or tantrums. If the feeder responds to these maladaptive behaviors by removing the disliked food or ending the meal, the child may repeat the maladaptive behavior the next time a meal is served. If this happens repeatedly the maladaptive behavior becomes a learned response. In Harry’s case, he will not even start eating without distraction, and the more difficult he becomes, the more powerful the distraction becomes. He has learned that batting the spoon causes his mother to pull the spoon away and delay the presentation, so batting has become persistent. If he refuses persistently enough, she will even get him out of the chair and feed him without a spoon while he is playing. Refusal gets rewards!

DIAGNOSIS AND CLINICAL MANIFESTATIONS

Diagnosis of what qualifies as a real feeding problem can be difficult in that children go through multiple feeding transitions in the first 2 years of life and may need time to integrate the higher skill, depending on how much practice they get and how motivated they are to eat. However, if the child has had difficulty with previous feeding milestones, the feeding concern is more likely a feeding problem.

Aspiration/Penetration

Aspiration refers to food or a foreign substance entering into the airway (Figures 29.6). It may occur before, during, or after a swallow or as a result of reflux. Everyone aspirates small amounts of food occasionally, but our protective responses—gagging and coughing—help to clear them from the airway. Children with developmental disabilities that affect sensory or motor coordination of the oropharynx, larynx, or trachea, however, are at increased risk for recurrent aspiration (Jadcherla et al., 2010). Furthermore, these children often have impaired protective responses that limit their ability to clear their airway once aspiration occurs. Signs of aspiration are influenced by the age of the child. In infants, it may present as apnea and bradycardia (slowed heart rate) during meals, whereas in older infants and children, it may appear as coughing, congestion, or wheezing. Some children aspirate without a protective response from the body; this is called silent aspiration and is particularly dangerous because it often goes undetected. Recurrent aspiration and resultant accumulation of foodstuffs in the airway cause irritation and inflammation that can lead to pneumonia,

bronchitis, or tracheitis (Jadcherla, 2016). If aspiration is suspected, a multidisciplinary feeding team should see the child to evaluate if aspiration is occurring, and, if so, why (Dodrill & Gosa, 2015).

Difficulty Advancing Texture

Coughing and Gagging Coughing and gagging indicate difficulty with swallowing. Both are normal defense mechanisms used to prevent aspiration. Coughing and gagging during the meal may indicate troublesome food textures. For example, if a child gags on lumpy foods but not on purées, it indicates difficulty adequately chewing or transporting the more highly textured food. Harry's ineffective transport pattern contributed to his gagging on lumps and thicker purées. The child who coughs while drinking may have a problem controlling flow through the pharynx and past the airway. If the child coughs or gags at the end of or after a meal but not during the meal, GER should be considered. Persistent coughing or gagging during meals over several weeks is a serious warning sign and requires a swallowing evaluation as soon as possible (Rybak, 2015).

Figure 29.6. A) If a part of the bolus leaks past the soft palate before a swallow is triggered, it can flow past the open epiglottis and into the trachea. B) If the epiglottis is not completely closed as the bolus passes, aspiration can also occur. C) Food residue in the pharynx after a swallow can be carried into the airway with the next breath, resulting in aspiration after the swallow.

Choking Choking occurs when food becomes stuck in the pharynx. This happens most commonly when large pieces of soft solids are given to a child whose munching pattern or suckle transport is inadequate or if the child tends to stuff his or her mouth before swallowing. Cutting foods up into smaller pieces or offering only a couple of pieces at a time may decrease choking. After some practice and with positive reinforcement, the child may be able to gradually increase the size and/or number of chunks accepted. Choking can also occur when there is dysfunction in the UES, as with GER, or when using the mouth as an airway while eating. A full evaluation can help to ascertain the etiology quickly and develop an approach to remediation if needed.

Food Pocketing Food pocketing (holding food in the cheeks or the front of the mouth for prolonged periods) suggests either problematic oral transport or food refusal. Children with difficulty moving their tongue from side to side or those who use an immature central transport pattern often have trouble transporting food back to the midline before a swallow. As a result, mashed food or chunks migrate toward the cheeks. Alternatively, if a child does not want to swallow the food because of its texture or taste, he or she may trap it in the cheeks or under the tongue. Some children with a persistent suckle pattern will move each food bolus to the front of the mouth just behind the front teeth before trying to swallow it. Often this will lead to build up of residue and pooling under the tongue.

Increased Oral Losses Loss of food from the mouth, or “messy eating,” may signal an oral-motor problem, whether related primarily to the oral pharyngeal musculature or to the impact of medical or postural conditions on oropharyngeal function. The child may have poor lip closure or jaw instability caused by abnormal tone in the facial muscles. As a consequence, once in the mouth, food may 1) be carried out onto the tongue as a result of a persistent suckle pattern or exaggerated tongue thrust; 2) fall out of the mouth if the child has not practiced an active transport pattern; or 3) be expelled in an attempt to control bolus size, as when there is swallowing difficulty related to GER or throat infection. Sometimes food may be exhaled from the mouth if the oral cavity also serves as the primary airway.

Prolonged Feeding Time

Prolonged feeding time (greater than 30 minutes) usually results from a combination of factors. Oral transport may be slowed by difficulty in collecting food in

the mouth or by weakened tongue movements. The suckling pattern of infants with a history of prematurity or cleft palate may utilize more compression than suction. This limits the negative pressure they can generate with which to extract liquid from a nipple and slows the rate of feeding. If pharyngeal transfer is weak or uncoordinated, the child may need more swallows between bites to clear the food bolus from the pharynx. The child may also slow the meal to allow more time for breathing between bites or to complete transport through the esophagus. The child may appear at times to take breaks, or dawdle, during a meal to allow time for gastric emptying. Prolonged feeding time is a difficult problem for both the child and caregiver and signals the need for an evaluation (McCornish et al., 2016). In Harry's case, his mother is unable to get an infant spoonful of food into his mouth because of his oral defensiveness. Furthermore, she is not able to place it on his tongue because his tongue is very retracted.

Avoidant/Restrictive Food Intake Disorder

ARFID, as described earlier in this chapter, is a new diagnostic category that includes food refusal and food selectivity.

Food Refusal Food refusal can be total, in which case the child does not accept and swallow any food, or partial, in which the child eats some food but not enough to sustain adequate growth and nutritional health. Food refusal is most often associated with an ongoing medical problem such as asthma or GER. Because of the resulting lack of practice eating, these children's oral-motor skills are also commonly immature or dysfunctional, which further complicates matters. Food refusal requires a coordinated approach among an interdisciplinary team of physicians and therapists (Dodrill & Gosa, 2015; Lukens & Silverman, 2014; Phalen, 2013; Sharp, Volkert, Scahill, McCracken, & McElhanon, 2017).

Food Selectivity Food selectivity implies that the child will accept only a small number of foods, although he or she may eat large quantities of them. Children with ASD often display selectivity of foods (see Chapter 18). Texture-focused selectivity is most commonly seen in children with cerebral palsy who have oral-motor problems. Selectivity may initially stem from an underlying medical condition but then becomes a learned response perpetuated by environmental or interactional factors even after the instigating factor has been resolved (Clawson & Elliott, 2014; Lukens & Silverman, 2014). Food selectivity is a difficult problem that, like food

refusal, requires the coordinated efforts of an interdisciplinary team (Lukens & Silverman, 2014).

MONITORING, SCREENING, AND EVALUATION

As children learn how to eat through neurologic maturation and successful practice, it is of utmost importance to ask about feeding skills and mealtime interactions at every well-child visit. Following growth parameters can also be helpful, but they are not sensitive to early stages of a feeding problem. Moreover, children may continue to grow normally for some time despite nutritional risk from severe food selectivity or markedly prolonged feeding times that would signal a feeding problem.

Multiple screening tools are available to help differentiate a normal feeding phase from a feeding problem, although there is not one that is universally accepted. Because of the complexity of the feeding process and the multiple influences on it, investigation of a feeding problem should employ a multidisciplinary perspective (Lukens & Silverman, 2014; McCornish et al., 2016; Phalen, 2013). Information is needed regarding how and when the feeding problem started, how it has changed over time, and what interventions have been used. Background information regarding the child's medical, motor, and behavioral history is also important. A thorough evaluation includes the child's medical history, a physical examination, a neurodevelopmental assessment, an oral-pharyngeal evaluation, feeding history, and mealtime observation (McCornish et al., 2016). A nutritional analysis of a 3-day record of the child's intake can provide helpful information regarding the total calories ingested, vitamin and mineral content, and nutritional balance of the diet (McCornish et al., 2016). The information gleaned from the evaluation will identify the feeding problem and the medical, motor, and motivational factors contributing to it (Kerzner et al., 2015).

Diagnostic procedures may be needed to provide further information to support or clarify the clinical impression. Films of the airway can aid in detecting upper airway obstruction. If aspiration of oral feedings is suspected, a modified barium swallow (MBS) with video fluoroscopy is commonly used. In this procedure, the child is placed in the usual feeding position and offered foods to which barium, a milk-like substance visible on x-ray, has been added. The radiologist uses a video fluoroscope to visualize the pharynx and watch how the pharyngeal muscles guide the food bolus past the airway. The texture of the food and liquids can be varied to evaluate how the child's swallowing function changes with different textures. Video fluoroscopy can also give information about airway size and the

interface of swallowing and respiration. Flexible endoscopic evaluation of swallowing (FEES) has become more frequently used in evaluating swallowing dysfunction. With FEES, a small endoscope is inserted into the nose and passed to the back of the throat in order to directly visualize the hypopharynx (where the larynx, the entrance to the lungs, sits next to the entrance to the esophagus). The endoscopist can see whether some of the bolus has entered the airway before, during, or after the swallow. The drawback of this procedure is that the area cannot be captured via the camera during a swallow, so the exact mechanism of the aspiration/penetration may not be clear. FEES with sensory testing can yield important information about the sensory thresholds of the area, information that is unavailable from the MBS (Dodrill & Gosa, 2015).

If GI dysmotility is suspected, an upper GI series can be done to rule out anatomical problems. For this procedure, barium is either ingested by the child or infused into the stomach by a nasogastric (NG) tube. As the fluid moves through the esophagus, stomach, and small intestine, the radiologist can identify structural abnormalities (Figure 29.2; Rybak et al., 2017). A second procedure, the milk scan or gastric-emptying study, provides information about height and frequency of GER episodes and assesses the rate of gastric emptying (Figure 29.7; Rybak et al., 2017). During the milk scan, the child swallows a formula to which a small amount of a radioactive tracer has been added, enabling the radiologist to track the milk as it moves through the GI tract. In addition, if the radioactive tracer is found in the lungs after several hours, it suggests that aspiration has occurred during a reflux episode.

The final two tests, the pH probe and gastroesophageal duodenoscopy (endoscopy), are considered the gold standards in the evaluation of GER and esophagitis, respectively (Edeani, Malik, & Kaul, 2017). For the pH probe, an NG-like tube is inserted through the nose and passed down the esophagus to just above the junction of the stomach and esophagus. At the tip of the tube is a small sensor, which detects the pH, or acidity, above the gastroesophageal junction. If acid in the stomach refluxes into the esophagus, the sensor records a sudden drop in the pH level, signaling GER (Figure 29.8). A symptom diary or videotaping of the child's activities and behaviors during the study period enhances the interpretation of the pH changes. A relatively new technology, multiple intraluminal impedance (MII), measures the movement of fluids, solids, and air in the esophagus. MII and pH electrodes should be combined on a single catheter. This combination can detect extremely small amounts of refluxed material, whether or not it is acidic (Edeani et al., 2017). Endoscopy entails passing a fiberoptic tube through the mouth down the

Figure 29.7. In this study, the child is fed a milk formula containing minute amounts of a radioactive label that can be seen on scanning. A) Shown here is a sequence of images taken after the child drinks the milk. The images are generated by a computer from information obtained by the scanner every 120 seconds. The area of radioactivity at the top of each image represents residual formula in the mouth, whereas the lower area of radioactivity is the stomach. Images 34 to 39 show increased activity in the mouth and esophagus, reflecting a reflux episode to the mouth and descending back to the stomach. In images 44 to 48, radioactivity can be seen flowing up from the stomach into the midesophagus, indicating another episode of reflux. A repeat scan after the child was placed on antireflux medication would show an absence of stomach reflux. B) In addition to diagnosing reflux, the milk scan can also evaluate whether the stomach is emptying food into the small intestine at a normal rate. Delayed gastric emptying (GE) increases stomach pressure and the possibility of reflux or vomiting. In the study shown, residual gastric radioactivity decreased by 15% 1 hour after the labeled milk was ingested (decreasing from 1.370×10^5 counters per minute to 1.162×10^5). This 85% 1-hour residual is high, as the normal is 67% or less. Prokinetic agents such as metoclopramide (Reglan) not only decrease gastroesophageal reflux directly, but also indirectly by increasing GE. Following effective medication, the rate of GE would be expected to increase, potentially to normal levels.

esophagus and into the stomach. The child is sedated during this procedure. The gastroenterologist can then look directly at the esophagus and stomach and take small biopsy specimens to look for signs of inflammation, allergy, or infection with organisms such as *Candida* or *Helicobacter pylori* (Edeani et al., 2017).

TREATMENT, MANAGEMENT, AND INTERVENTIONS

Because feeding problems in children with neurodevelopmental challenges usually result from the interaction

Figure 29.8. A pH probe study is done by passing a tube containing a pH electrode down the esophagus and positioning it just above the stomach. If there is reflux, the pH should drop as the acid contents of the stomach reach the lower esophagus, where the probe is placed. Shown here is an abnormal study with multiple episodes of low pH, occurring about half an hour after feeding and when the child is laid down to sleep. (From Batshaw, M. L. [1991]. *Your child has a disability: A complete sourcebook of daily and medical care* [p. 224]. Baltimore, MD: Paul H. Brookes Publishing Co., Inc.; reprinted by permission. Copyright © 1991 Mark L. Batshaw. Illustration copyright © 1991 by Lynn Reynolds. All rights reserved.)

among multiple factors, managing such problems can be difficult, time consuming, and frustrating (Box 29.1). Effective treatment usually requires intervention from more than one therapeutic discipline, and any plan of intervention must be potentially applicable across all of the child's environments (home, school, and therapist's office) to be truly effective. The treatment team, which should include the child's caregiver, teacher, medical care provider(s), and therapists, needs to prioritize the treatment goals and outline a plan integrating the child's medical, nutritional, and developmental needs (Brackett, Eicher, Kerwin, & Fox, 2012). The primary caregiver, with team input, oversees the plan and monitors progress toward the goals; however, open lines of communication among all team members are crucial. Components of a successful treatment strategy include 1) minimizing negative medical influences, 2) ensuring positioning for feeding, 3) facilitating oral-motor function, 4) improving the mealtime environment, 5) promoting appetite, and 6) using alternative methods of feeding (if needed).

All of these components entail constant monitoring of the child's progress. Recognizing the interactions among the medical, motor, and motivational components enables the team to anticipate changes and treat several components at the same time (Brackett et al., 2012). Obviously, for a feeding program to be successful, the therapists need to be consistent and mindful of how the skills they are forging will affect the child's feeding function.

BOX 29.1 INTERDISCIPLINARY CARE**Family Counselor**

The family counselor provides support and recommendations to reduce the stress that affects the whole family because of a child's feeding problem. They also help the family find the strength necessary to carry out the new mealtime protocols and change existing family interaction patterns that are detrimental.

Minimize Negative Medical Influences

Because feeding is a complex skill, a child's feeding function may be very sensitive to even minor medical issues. Thus, parents' and therapists' observations of subtle changes in the child's behaviors, especially during and after feedings, are important and should be shared with medical care providers. Problems with GI irritation and dysmotility can adversely affect respiratory and GI function, as well as the child's level of comfort, and should be treated. For example, Harry is able to drink a bottle sitting up, and his mealtime resistance decreases when he has daily, mushy stools that are not dependent on gastric filling to stimulate evacuation. In fact, his tongue retraction decreases with an improved stooling pattern. Constipation can be remediated by 1) establishing regular toileting times to take advantage of the gastrocolic reflex that occurs after meals; 2) providing adequate fluids to minimize dry, cakey stools; and 3) encouraging active or passive physical exercise. Dietary fiber in the form of fruits, vegetables, and whole-grain foods can also increase movement through the GI tract, although more explicitly fiber-intensive products (e.g., Metamucil or Benefiber) may also be helpful (Tabbers et al., 2014).

When constipation is persistent, additional measures may be needed. To effectively manage persistent constipation, the colon needs to be cleared of stool, and then the child needs to have at least one stool daily with the use of a consistent regimen of appropriate laxatives, if needed, which work to soften the stool and/or stimulate evacuation. Laxatives and suppositories can be used, including milk of magnesia, senna concentrate (Senokot), bisacodyl (Dulcolax), lactulose, polyethylene glycol, or glycerin suppositories (Tabbers et al., 2014). Enemas, such as the Fleet Enema for Children, also may help, but continuous use of enemas can interfere with normal rectal sphincter control and should be avoided. A combination of the discussed approaches may be needed to establish regular bowel movements.

If GI irritation or GER is present, a number of therapeutic modalities are available, including proper

positioning, meal modification, medications, and surgery (Rybak et al., 2017). The goal is to minimize gastric irritation and protect the esophagus from reflux of stomach acid, either by reducing the amount of gastric contents or by decreasing stomach acid production. Small, frequent meals help to decrease the volume of food in the stomach at any one time. In addition, studies show that whey-based formulas improve stomach emptying and decrease vomiting in children with certain forms of spastic cerebral palsy (Minor, Ochoa, Storm, & Periman, 2016). Similarly, a change in formula to a different protein source or predigested protein may alleviate irritation in those children with milk or soy protein intolerance (Rybak et al., 2017). Upright positioning and thickened feedings simply rely on gravity to help keep stomach contents from refluxing into the esophagus. Recent research with premature infants shows that side-lying positions can significantly increase the rate of emptying after a feeding, which then can be used to minimize reflux after the meal. As for medications, H₂ antagonists (cimetidine [Tagamet], ranitidine [Zantac], and famotidine [Pepcid]), as well as proton pump inhibitors (omeprazole [Prilosec], lansoprazole [Prevacid], and esomeprazole [Nexium]) decrease stomach acidity and thereby lower the risk of reflux-caused inflammation of the esophagus (Rybak et al., 2017). Motility agents such as urecholine (Bethanechol), metoclopramide, and erythromycin increase the tone or movement in the esophageal sphincter and stomach, making it harder for reflux to occur (Rybak et al., 2017).

When GER cannot be controlled by positioning and medication alone, surgery may be needed to prevent problems associated with prolonged reflux. These problems include poor weight gain, recurrent aspiration pneumonia, esophageal stricture, and recurrent apneic episodes (Garipey & Mousa, 2009). The most common surgical procedure is fundoplication, in which the top of the stomach is wrapped around the opening of the esophagus (Figure 29.9). This decreases reflux while permitting continued oral feeding. An alternative to fundoplication is surgically placing a gastrojejun- (G-J) tube that allows access to the stomach as well

Figure 29.9. In the surgical procedure of fundoplication, the upper stomach is wrapped around the lower esophagus to create a muscular valve that prevents reflux.

as the jejunum, permitting some portion of the feeds to bypass the stomach and thereby decreasing the risk of reflux (Figure 29.10; Garipey & Mousa, 2009).

Ensure Proper Positioning for Feeding

Feeding is a flexor activity that requires good breath support. Appropriate positioning maximizes the child's ability to breathe as well as providing the best alignment to optimize function of the muscles involved in the swallowing process (Larnert & Ekberg, 1995). The child should be firmly supported through the hips and trunk to provide a stable base. The head and neck should be aligned in a neutral (upright) position, which decreases extension through the oral musculature while maintaining an open airway (Figure 29.11). Such positioning improves coordination and control of the steps in oral-motor preparation and transport. This, in turn, results in more positive feedback to the child and caregiver as a result of good feeding experiences (Brackett et al., 2012). If the child does not appear comfortable or appropriately supported for feeding in the currently constructed chair, the child's occupational or physical therapist can make changes to improve the support and alignment (Box 29.2). In the case study, Harry is positioned in the highchair with the shoulder straps adjusted snugly, and the iPad is elevated so that his head is held in a neutral position.

Facilitate Oral-Motor Function

Any technique that eases the child's practice of an oral-motor pattern correctly facilitates oral-motor function.

Figure 29.10. The nasogastric (NG) tube is placed through the nostril and into the stomach. An NG tube is helpful when problems with the child's oral function are the primary obstacle to adequate nutrition and are temporary. A gastrojejunal (G-J) tube allows access to the stomach as well as directly into the intestine. The G-J tube has two openings, or ports, and two parts of tubing. The G port connects with the G tube, which empties the stomach. The J port connects with the J tube, which empties into the intestine. A G-J tube can be helpful when the stomach is unable to tolerate the quantity of nutrients needed for adequate growth.

It may consist of oral-motor stimulation or desensitization without food, specific placement of food, or manipulation of the food to make it easier for the child to control. Recent research with premature infants has demonstrated that providing patterned orocutaneous stimulation that mimics the temporal organization of sucking can enhance the premature infant's acquisition of a functional suckle pattern, thereby decreasing the time needed to establish nipple feedings and then attaining full oral feeding (Barlow, Finan, Lee, & Chu, 2008). In older infants, chin support can often facilitate transition of the tongue pattern from a suckle to sucking and later to tongue lateralization (Gisel, 2008). Chewing can be enhanced by placing food between the upper and lower back teeth, which stimulates crushing movements of the jaw as well as lateral movement of the tongue, both of which are needed to master a munching pattern. Another technique is manipulating food textures to facilitate safe, controlled swallowing (Dodrill & Gosa, 2015). Thickening of liquids slows their rate of flow, allowing more time for the child to

Figure 29.11. A) A child with a neutral pelvis and adequate trunk support to allow neutral positioning of the head and neck. Note how the ears and shoulders align in the same plane as the hips. B) A child supported in a slightly reclined seated position in which the ear, shoulder, and hip remain aligned. This would be a good position for a child who does not have adequate head control to maintain head and neck alignment during a mealtime.

organize and initiate a swallow. Thickening agents (e.g., Thick-It or instant pudding powders) can transform any thin liquid into a nectar-, honey-, or milkshake-like consistency (Box 29.3). In addition, almost any food can be finely chopped or puréed to a texture that the child can more competently manage.

It is important to remember that the primary goal of eating is to achieve adequate nutrition. Thus, when a child is first learning to accept a higher texture of foods, these foods should be presented during snack time, when volumes are smaller. During this transition period, easier textures should be used at mealtimes to

ensure consumption of adequate calories for continued growth (Box 29.4). A speech-language pathologist or an occupational therapist can provide information about the child's oral-motor patterns and the appropriate food textures to facilitate improvement in feeding efforts.

Improve the Mealtime Structure

Eating requires more coordination among muscle groups than any other motor activity, including speech. Therefore, it is important to make eating as easy as possible. This can be accomplished by increasing the

BOX 29.2 INTERDISCIPLINARY CARE

Occupational and Physical Therapists

The motor therapists evaluate rib cage mobility and breathing, posture and alignment, and core development and activation in gross motor function, in addition to fine motor skills and sensory functioning. Their input is crucial in optimizing posture and alignment during mealtime as well as appropriate utensil use and necessary adaptations when working on self-feeding. Motor therapy works on ribcage mobilization to enhance respiratory support as well as strengthening activities for the shoulder girdle, trunk rotation, and the core to support optimal posture and alignment for feeding. If the child has sensory issues, such as those manifested by increased sensitivity to different clothing textures, grass, sand, and so on, the occupational therapist can recommend activities to help desensitize the child and therapies to further decrease their hypersensitivity.

BOX 29.3 INTERDISCIPLINARY CARE**Nutritionist/Dietician**

The nutritionist helps to evaluate the adequacy of the child's current diet regarding caloric intake and nutritional quality. They can recommend appropriate changes to enhance the child's diet, satisfying the child's caloric and nutrient needs while also providing nutritional balance.

child's focus on the meal and including desirable foods in each meal that are easier to control. The caregiver should let the child know that mealtime is coming so that he or she can prepare for the "work" to be done. This may entail a pre-mealtime routine of going to a special corner of the room and putting on a bib or napkin or performing relaxation therapy, followed by oral stimulation to get the needed muscles ready for eating. Children with feeding difficulties usually eat better in one-to-one situations or in small groups because there are fewer distractions, aiding the ability to focus on the eating process (Clawson & Elliott, 2014). Parental provision of undivided attention also makes mealtimes more reinforcing.

When working on improving or advancing skills, it is important to break the skill down into small tasks that can be practiced with motivation (Sharp et al., 2017; Box 29.5). The child can be successful and ready to couple it with the next step in the process. When a child is eating well and interested in self-feeding, a number of adaptive devices can promote independence in eating. These include bowls with high sides, spoons with built-up or curved handles, and cups with rocker bottoms. The satisfaction that children obtain from eating can be increased by social attention during the meal or earning time for a favorite activity after the meal is completed.

Social interaction is an important part of mealtime as well, although it can be distracting. When peer

interaction is the focus, it may be helpful to make the meal small (e.g., a snack) and to provide less challenging foods that do not require as much concentration for the child to successfully eat.

Promote Appetite

Some children have little or no appetite regardless of whether they are receiving enough calories to progress along their growth curve. This may be caused by an underlying medical condition, such as a kidney or metabolic disorder or zinc deficiency, or it may be a sign that a chronic medical condition (e.g., diabetes) is inadequately controlled. Alternatively, some children's appetites may be poor as a consequence of being satiated by their snacking, drinking, or supplemental feedings (Hartdorff et al., 2015). Eating "real" food at mealtimes represents more work to many children with feeding problems than does drinking or grazing on snack foods. Thus, these options can satiate the child and decrease their motivation to eat at mealtimes further. Set meal and snack times in addition to limiting access to fluids for an hour before meals can be helpful to eliminate grazing and promote appetite.

When underlying causes of poor appetite have been addressed, medications to promote appetite may be helpful. Cyproheptadine (Periactin) is a serotonin antagonist that works to increase appetite through two

BOX 29.4 INTERDISCIPLINARY CARE**Speech Therapist**

The speech therapist on the team helps to evaluate tongue movement with and without food in the mouth. They facilitate more successful oral motor patterns by manipulating the texture or placement of food in the oral cavity. They may also recommend exercises to work on increasing tolerance to new stimuli in the mouth or stimulating appropriate oral motor patterns. The speech therapist can be very helpful during a modified barium swallow in performing the test with appropriate textures to elucidate the swallowing problem, as well as interpreting the results.

BOX 29.5 INTERDISCIPLINARY CARE**Behavioral Therapist**

The behavioral therapist evaluates the antecedents and consequences contributing to the child's interactional behaviors at mealtime. They can recommend structured mealtime protocols to help enlist the child's cooperation to practice more appropriate feeding patterns. In addition, they can provide recommendations for behavioral problems that may be occurring outside of mealtimes.

mechanisms. It has a central effect to increase appetite and also affects the GI tract to enhance volume tolerance (Krasaelap & Madani, 2017; Rodriguez, Diaz, & Nurko, 2013).

There are differing opinions about whether day versus night, or bolus versus continuous, tube feedings are better for promoting appetite (Dsilna, Christensson, Alfredsson, Lagercrantz, & Blennow, 2005; Dsilna, Christensson, Gustafsson, Lagercrantz, & Alfredsson, 2008). Actually, the important thing is to look at how the child is tolerating the tube feedings. If the child retches, gags, vomits, or needs time to recover after tube feedings, he or she is not tolerating them. Sometimes it takes hours for the child to feel comfortable enough to eat orally again. With this in mind, the best tube-feeding schedule to promote a child's appetite is the one that is tolerated without GI discomfort, even if this involves continuous feedings. Once the child's feeding skills have improved, tube feeding volume can be gradually decreased to further promote appetite.

Use Alternative Methods of Feeding

In some cases, oral feeding may not be safe or sufficient to permit adequate nutrition (Mahant, Friedman, Connolly, Goia, & Macarthur, 2009; Quitadamo, Thapar, Staiano, & Borrelli, 2016). For these children, NG tube feedings or the placement of a gastrostomy (G) or G-J feeding tube is required (see Figure 29.10). A commercially prepared enteral formula (e.g., Nutren Jr. or Pediasure) can be used with any of these tubes. Although puréed table food feedings can be given through an NG or a G tube, they are not appropriate for a jejunostomy (J) tube because they will obstruct it. With an NG or a G tube, feedings can be given as single large volumes (boluses) of 3 to 8 ounces every 3–6 hours or as a continuous drip throughout the day or overnight. J-tube feedings must be given continuously, not as a bolus. The advantage of large-volume

feedings is that they do not interfere with typical daily activities. The feeding itself takes about 30 minutes. As mentioned previously, however, the large volume may be difficult for the child to tolerate and may lead to vomiting or abdominal discomfort. If this happens, continuous-drip feedings can be instituted. A Kangaroo or similar type of automated pump is then used to deliver the formula at a set rate. Sometimes tube feedings are used to supplement oral feedings. In this case, tube feedings generally are used at night so that the child remains hungry for oral feedings during the day. A nutritionist can recommend the appropriate type of enteral formula as well as the amount of supplementation necessary to provide a nutritionally balanced intake that meets the child's daily caloric needs.

OUTCOMES

Although difficult, feeding problems can be effectively treated if the intervention strategy takes into account the many factors contributing to the feeding problem. In fact, multidisciplinary intervention is now the accepted standard of care for the treatment of pediatric feeding problems (Lukens & Silverman, 2014; Sharp et al., 2017). A recent review of published studies looking at children with complex medical conditions and tube dependence receiving inpatient or day treatment services reported intervention strategies incorporating components from medicine, psychology, speech or occupational therapy, and nutrition. Reportedly, on aggregate at discharge, 71% of these children no longer needed tube feeding, and there was maintenance or continued improvement for 80% of children on follow-up after discharge (Sharp et al., 2017). Thus, there is preliminary evidence to support the positive effects and long-lasting benefits of multidisciplinary treatment. Future research is needed to better define the various types of feeding problems and the disciplinary interventions necessary to most effectively treat them.

SUMMARY

- For children, feeding is complicated by the changes to the swallowing process that typically occur with growth and development.
- Feeding problems are very common for all children, but even more so for children with neurodevelopmental challenges.
- Feeding problems may result from an anatomical, medical, or developmental issue that interferes with successful swallowing. However, the initial problem is often compounded by interaction of ongoing medical, motor, and behavioral issues as time passes.
- More commonly, feeding problems may result from the influence of medical, motor, developmental, and/or interactional factors on the swallowing process, thus interfering with the typical oral-motor progression in the attainment of feeding skills.
- Evaluation of a child with a feeding problem requires an understanding of the normal feeding process and insight from medical, motor (oral, fine, and gross), and behavioral perspectives to accurately identify the factors contributing to the feeding problem.
- Effective intervention requires multidisciplinary input to optimize the child's feeding function while enabling adequate growth, development, and social interaction.

Interventions

CHAPTER 30

Interdisciplinary Education and Practice

Lewis H. Margolis and Angela McCaffrey Rosenberg

Upon completion of this chapter, the reader will

- Define the attitudes and skills that constitute interdisciplinary education and practice
- Explain the origins and ongoing evolution of interdisciplinary education and practice
- Underscore the value of interdisciplinary practice for the emerging field of children with medical complexity
- Highlight family members as key interdisciplinary partners
- Identify challenges in measuring the effects of interdisciplinary education and practice
- Outline characteristics to advance and sustain interdisciplinary education and practice

In the 21st century, families live in an increasingly complicated and complex world, challenged by globalization (Gerhardt, 2016); demographic shifts, such as changing family composition (Child Trends, 2015); an aging population (Ortman, Velkoff, & Hogan, 2014); increasing cultural diversity (Colby & Ortman, 2015); and a growing prevalence of disabilities (Boyle et al., 2011). At the same time, many basic science and clinical disciplines are becoming more specialized as knowledge and understanding continue to evolve, sometimes at a dramatic pace.

To address the increasing complexity of public health and medical care, national and international entities and scholars have encouraged educators and clinicians to develop programs that enhance the

capacity of professionals to collaborate. A variety of groups have suggested that some combination of dedicated interdisciplinary, or interprofessional, education and intentional practice are critical to creating competent professionals. For example, *To Err Is Human*, a report by the Institute of Medicine about patient safety, calls for organizations to “establish interdisciplinary team training programs for providers” (Kohn, Corrigan, & Donaldson, 2000, p. 14). Frenk and colleagues (2010) have promoted a competency-based approach to educating health professionals in which teamwork, or collaboration, is a core competency, and the Interprofessional Education Collaborative (2016) has underscored the need for a seamless transition from education to collaborative practice. In addition, in 2015, the Institute

of Medicine convened a committee to move “beyond examining the impact of IPE [interprofessional education] on learners’ knowledge, skills, and attitudes to focus on the link between IPE and performance in practice including the impact of IPE on patient and population health and health care delivery system outcomes” (2015, p. 2).

Given the multifaceted aspects of growth and development, as well as the cultural contexts for children, both with and without disabilities, and the families in which they reside and ideally flourish, the professional field of maternal and child health, especially those professional disciplines educated and engaged in the care of children with disabilities, needs to be intentional in advancing collaboration to enhance the well-being of these children and their families.

This chapter traces the institutional development of interdisciplinary approaches and identifies knowledge, attitudes, and skills that define interdisciplinary education and practice. As a way of encouraging the development of this important set of skills, the chapter reviews what still remains a limited body of literature on the effects of interdisciplinary education and practice. It concludes with suggestions for strategies to implement and advance interdisciplinary practice to achieve optimal outcomes for children with disabilities and their families.

■ ■ ■ CASE STUDY

Imagine that you are a clinician on an interdisciplinary team that provides assessment and rehabilitation services for children with disabilities. You have been on this intact team for 5 years. Your team has had impressive synergy, and, due to similar team processes and approaches, the majority of you get along well. You feel you can often anticipate what your team members will recommend regarding treatment plans, and your own professional input is appreciated.

Overall, this organization has been a positive work environment, but you miss your team leader, who recently retired. She was the central core of the group, hired you, and was an excellent clinician. She set up the team meeting structure and policies by which you operate. Now you have a new team leader, and you are not sure about how she will contribute to the group. She seems to be changing the team structure and processes in ways that you feel are not well thought out. You also have one new team member who is, frankly, difficult, often bringing up seemingly irrelevant issues or ideas that just aren’t practical for children. You and other team members have begun to tune out when this person begins to speak.

Today you are having a team meeting about how best to partner with a family in treatment planning. The

mother seems challenging to some. The family recently relocated to the area, and the mother brings up how much better the “other state” was in providing services, questioning the quality of some of the services her child is receiving.

Thought Questions:

As a clinical provider or as a student who may be observing, consider a recent team-based clinical encounter that did not seem as effective as you had hoped for or expected. Putting aside whatever complexities and uncertainties of the child’s clinical condition that may have complicated the encounter, reflect on the characteristics of the team that may have contributed to your feelings or conclusions. What assumptions may have been made by team members, including the family, that made the encounter less effective? What interdisciplinary skills were in play? Could specific skills have advanced the discussion and plans for the child and family? When your team encounters challenging interdisciplinary situations, do you intentionally seek advice from professionals who think differently than you? If so, what insights have you gained? If not, what prevents you from doing so?

DEFINING INTERDISCIPLINARY EDUCATION AND PRACTICE

Interdisciplinary practice, defined as “collaborative practice that combines the insights of several professional disciplines, consumers, and community members—in designing care or programs” (Margolis, Rosenberg, Umble, & Chewning, 2013, p. 950), is central to the clinical care and policy development for children and youth with special health care needs (CYSHCN). Although the term *interprofessional* has gained ascendancy, this chapter intentionally uses the term *interdisciplinary* because it reflects respect for all of the many different partners who engage in collaboration to advance the well-being of children and their families. The term *interprofessional* places professionals, with all the training and expertise the term implies, at the core of education and practice. This is reflected, for example, in the World Health Organization definition, “when multiple health workers from different backgrounds provide comprehensive services by working with patients, their families, care givers and communities to deliver the highest quality of care across settings” (2010, p. 13). The expertise of parents is at the core of providing high-quality care and services for CYSHCN. According to the National Center for Family/Professional Partnerships of Family Voices (2018),

Family-centered care is a way of providing services that assures the health and well-being of children and their families through respectful family/professional partnerships. It honors the strengths, cultures, traditions, and expertise that families and professionals bring to this relationship. Family-centered care improves the patient's and family's experience with health care, reduces stress, improves communication, reduces conflict (including lawsuits), and improves the health of children with chronic health conditions.

Roger Schwarz, an internationally recognized expert on team leadership, highlights five assumptions that illuminate and enrich the dynamics of interdisciplinary practice and expand one's lens beyond profession and discipline (Schwarz, 2013). These assumptions underpin what he describes as a mutual learning approach, an approach that strengthens teams of all types and combinations. In considering teams that might work with children with disabilities, these teams could comprise clinicians working to diagnose a challenging condition; partnerships between families and clinicians caring for a child who has a complex social situation; or social workers, educators, and other community service providers working with parents to manage or coordinate the systems of care for a child with special health care needs.

Schwarz's (2013) assumptions about teaming include the following:

1. I have information; so do other people.
2. Each of us sees things that others don't.
3. Differences are opportunities for learning.
4. People may disagree and still have pure motives.
5. I may be contributing to the problem.

These assumptions are highly relevant to engagement with and around the population of children with disabilities. For interdisciplinary practice to be effective, individuals from the many clinical and educational disciplines who interact must recognize that other disciplines, including families and self-advocates, bring their own perspectives and expertise, as well as personal preferences and challenges, which can make the translation of theoretical skills in the clinical practice setting daunting. For example, in the middle of an emotion-laden Individualized Education Program meeting with contrasting views on the continuation of therapies, participants should be aware of personal differences. For example, teams may consider each member's approach to and comfort with change (Discovery Learning, n.d.), conflict style (Killman Diagnostics, n.d.), and use of "thinking" and "feeling" or of "sensing" and "intuition" to understand and

approach problems (Myers & Briggs Foundation, n.d.). Evidence suggests that during times of conflict or high emotions, team members should employ knowledge of motivations, personality preferences, and discipline from the perspective of the "other." For example, the reluctance of a team member to make a firm decision related to discontinuation of a therapy may have more to do with their personality preference to remain open to additional information than an unarticulated desire to sabotage the decision.

The second assumption underscores the importance of respect among those who collaborate. The third assumption is perhaps at the very core of the concept of interdisciplinary care: By learning from one another—from parents, from children, from assorted clinical disciplines, or from organizational leaders who oversee services—there is value added to the engagement. The value is truly greater than the sum of the parts in addressing what can often be complicated challenges. The fourth assumption expresses the important role of compassion for one another in collaborative efforts. To be able to step back, be nonjudgmental, and assume the best about one another opens the way for new and creative insights into how to address challenges. The fifth assumption underscores the important skill of self-reflection; that is, the ability to explore within oneself, with humility, the motivations and values behind one's preferences and perspectives.

The Interprofessional Education Collaborative (2016) has outlined four competency domains (see Table 30.1).

The Interdisciplinary Leadership Development Program (ILDLP) at the University of North Carolina at Chapel Hill (Dodds et al., 2010) brought together graduate students, parents of children with special health care needs, state MCHB officials, and self-advocates to advance attitudes, beliefs, and skills in interdisciplinary practice. Table 30.2 shows questionnaire items that elicited attitudes and beliefs about interdisciplinary practice and captured the frequency of use of interdisciplinary skills 1–8 years after participation in the ILDP; the items were expressed as 5-point Likert rating scales (Margolis et al., 2013; Rosenberg, Margolis, Umble, & Chewning, 2015). These items reflect both the mutual learning assumptions and interprofessional collaborative competencies described above. The National Center for Interprofessional Practice and Education has become an important repository of tools to describe and assess interprofessional/interdisciplinary efforts (Brandt & Schmitz, 2017).

Engaging with parents on the interdisciplinary team provides an opportunity to reflect upon and employ Schwarz's assumptions as well as the skills and competencies described in Tables 30.1 and 30.2. In the

Table 30.1. Interprofessional education collaborative competency domains with selected competencies

Competency domains	Selected specific competencies
Values/ethics for interprofessional practice	Place the interests of patients and populations at the center of interprofessional health care delivery and population health programs and policies, with the goal of promoting health and health equity across the life span. Respect the unique cultures, values, roles/responsibilities, and expertise of other health professions and the impact these factors can have on health outcomes.
Roles/responsibilities	Communicate one's roles and responsibilities clearly to patients, families, community members, and other professionals. Recognize one's limitations in skills, knowledge, and abilities. Use unique and complementary abilities of all members of the team to optimize health and patient care.
Interprofessional communication	Choose effective communication tools and techniques, including information systems and communication technologies, to facilitate discussions and interactions that enhance team function. Listen actively and encourage ideas and opinions of other team members. Use respectful language appropriate for a given difficult situation, crucial conversation, or interprofessional conflict.
Teams and teamwork	Describe the process of team development and the roles and practices of effective teams. Apply leadership practices that support collaborative practice and team effectiveness. Use available evidence to inform effective teamwork and team-based practices.

From Interprofessional Education Collaborative. (2016). *Core competencies for interprofessional collaborative practice: 2016 update*. Washington, DC: Author.

Table 30.2. Questionnaire items to elicit interdisciplinary practice attitudes and beliefs and determine frequency of interdisciplinary skill use

Attitudes and beliefs about interdisciplinary practice

Providing services in interdisciplinary groups helps professionals become more sensitive to the diverse needs of consumers/patients than providing services as a single discipline.

The benefits of interdisciplinary patient care or program plans are worth the extra time it takes to communicate across disciplines.

The interdisciplinary approach reduces duplication and fragmentation in the delivery of care/services.

Providing services as an interdisciplinary group gets better results for consumers than working as single disciplines.

Interdisciplinary education should be a part of every health professional's preservice training.

I welcome the opportunity to collaborate with members of other disciplines.

I value the contributions of other disciplines to my work.

When I look for my next position, I will purposefully look for an opportunity where collaboration across disciplines is the norm.

Interdisciplinary skills

Assemble interdisciplinary group members appropriate for a given task.

Resolve conflicts in interdisciplinary groups.

Facilitate family-provider partnerships.

Effectively work with consumers with cultural backgrounds different from my own.

Effectively work other professionals with cultural backgrounds different from my own.

Coach coworkers in interdisciplinary practice.

Share ideas from my discipline with members of other disciplines.

Ask for insight or help from members of other disciplines to address a problem.

Use self-reflection to enhance my contributions to interdisciplinary work.

Establish decision-making procedures in an interdisciplinary group.

Develop a shared vision, roles, and responsibilities within an interdisciplinary group.

Critically evaluate information from other disciplines.

Evaluate how well an interdisciplinary group is working together.

Intervene to improve interdisciplinary group function.

(Reprinted with permission from Springer Nature. Maternal and Child Health Journal, 17[5]. Effects of interdisciplinary training on professionals, organizations and systems. 949–958. Margolis, L. H., Rosenberg, A., Umble, K., & Chewning, L. [2012]).

case study, for instance, the mother may have valuable insights into alternative service systems and care practices from her experience living in another state. Team members' expression of interest in her information is not only a chance to learn and build team trust, but may also provide a means to challenge the system status quo. Likewise, instead of dismissing a colleague's seemingly irrelevant discussion points, asking sincere questions will offer insight into his or her rationale and may lead to an improved plan of care for the child and family.

THE GROWTH AND DEVELOPMENT OF INTERDISCIPLINARY PRACTICE

Understanding the importance of bringing together multiple perspectives to advance the well-being of children has been the cornerstone of the evolution of programs and policies in the United States for more than a century. The legislation authorizing establishment of the Children's Bureau in 1912 noted multiple domains, including health, family, courts, and the workplace, pertaining to the welfare of children. Even the restriction on entering households, although intended to address the political concern over the intrusion of the federal government into private family life, expressed respect for families as partners in the care of children.

The Children's Bureau as the Legislative Foundation of Interdisciplinary Practice

The legislation authorizing establishment of the Children's Bureau noted the following:

The said bureau shall investigate and report to the Secretary of Health and Human Services, upon all matters pertaining to the welfare of children and child life among all classes of our people, and shall especially investigate the questions of infant mortality, the birth rate, orphanage, juvenile courts, desertion, dangerous occupations, accidents and diseases of children, employment, legislation affecting children in the several States and Territories. But no official, or agent, or representative of said bureau shall, over the objection of the head of the family, enter any house used exclusively as a family residence. The chief of said bureau may from time to time publish the results of these investigations in such manner and to such extent as may be prescribed by the Secretary. (Children's Bureau, 1912)

The first training programs supported by the U.S. MCHB in the late 1940s were motivated by the need

to develop professionals who could create services that enable children to benefit from the perspectives of multiple disciplines (Athey, Kavanagh, Bagley, & Hutchins, 2000). The move toward interdisciplinary practice gained legislative support with the passage of the Education for All Handicapped Children Act in 1975 (PL 94-142) and with greater emphasis in the Education of the Handicapped Amendments in 1986 (PL 99-457), especially Part C, which established early intervention services. Later amendments (PL 101-476 in 1990) resulted in the widely recognized Individuals with Disabilities Education Act (IDEA), further embedding interdisciplinary practice in legislative policy.

The Importance of an Interdisciplinary Approach to Children with Medical Complexity

According to Cohen and colleagues (2011, p. 529) children with medical complexity (CMC) have "medical fragility" and require "intensive care," two elements that alone demand the collaborative skills and perspectives of many disciplines and family members. The demand for a well-developed competency in interdisciplinary practice is further underscored by the additional phrase, "not easily met by existing health care models."

Advances in diagnosis and treatment have increased survival for children with even the most challenging of conditions. Still, the very low prevalence of CMC, estimated at 0.5% of the population of children (Kuo, Cohen, Agrawal, Berry, & Casey, 2011), should not be misleading, because the rate of increase of this population of children has resulted in tremendous demands. The costs—financial; emotional; and the time and attention of parents, clinicians, and educators—have prompted many models of care. Cohen and colleagues note, however, that "the evidence from examinations of clinical models of effective and efficient provision of health care for CMC remains remarkably limited. Existing care models include medical homes, co-management, and hospital-based and hybrid models that focus on care coordination" (2011, p. 532). Berry, Agrawal, Cohen, and Kuo (2013) and Allshouse, Comeau, Rodgers, and Wells (2018) further highlight the many, as-yet-unanswered, definitional, clinical, financial, health system, and family partnership questions for CMCs. The challenging nature of the conditions, in clinical terms, interpersonal demands, and stresses among institutional stakeholders (e.g., hospitals and insurers), suggests that attention to interdisciplinary competencies should be at the core of these many interactions.

The Role of Families

The intense demands on parents and family members in the care of CMCs and children with developmental disabilities underscore the importance of interdisciplinary skill development for parents as a key discipline. It is crucial to recognize that parents are likely to bring salient insights from the many social determinants (Artiga & Hinton, 2018) that influence their capacities to manage effectively the care of their children. For example, interdisciplinary practitioners must recognize that economic determinants, such as a parent's need to work both a day shift and an evening shift to pay a mortgage, may well impede their ability to follow through with well-meaning therapeutic recommendations for daily exercise regimens or parental social engagement. Similarly, inadequate community infrastructure, such as a lack of available transportation or the availability of affordable respite or child care, may prohibit parent attendance at meetings.

Many federal agencies and professional associations, including the MCHB, Family Voices, the American Academy of Pediatrics (Committee on Hospital Care and Institute for Patient- and Family-Centered Care, 2012), and others (e.g., the Association of University Centers on Disabilities), have articulated the important role of family members as partners with health professionals in providing care for CYSHCN. Indeed, performance measures to document the partnership role of family members have become part of the assessment process for MCHB training and service delivery programs (Maternal and Child Health Bureau, n.d.-a).

Family immersion in interdisciplinary education alongside clinical disciplines can influence their ability to partner both with their peers and health professionals. For example, families that engaged in the ILDP at the University of North Carolina reported enhanced skills in all six dimensions of collaborative family-professional partnerships described by Blue-Banning, Summers, Frankland, Nelson, and Beegle (2004): commitment, equality, trust, respect, communication, and appreciation of diversity of skills. As one parent participant explained:

I truthfully feel really fortunate that I've been able to help and watch the evolution of family members moving into more of a systems approach, but to also do it with this partnership. It has just been, I can't articulate enough or clearly, the benefit that I think will be derived from this, perhaps not tomorrow, but five years down the road, not only for the graduate students who hopefully one day will go "oh, that's what they were talking about," because we know that experiential learning kicks in, but also for the family members . . . who really

are sort of seeing themselves in a different frame and how powerful that is. I can't imagine the benefit any better than that." (Margolis et al., 2017)

As reflected in the case study, the departure of a respected team leader can precipitate a challenging period for team members. However, shifts in leadership are an excellent time to employ interdisciplinary leadership competencies. The new leader's changes in operational procedures, while initially perceived as premature, can pose an opportunity for team re-norming and perhaps expansion of interdisciplinary roles, a reenforcement of the concept of partnership.

MEASURING THE EFFECTS OF INTERDISCIPLINARY EDUCATION AND PRACTICE

On one level, interdisciplinary education involves increasing the understanding of the expertise that assorted disciplines bring to collaborative care. On another level, interdisciplinary education involves developing the capacity to utilize two fundamental insights, independent of discipline, that stem from the following two questions:

- What are my strengths, weaknesses, preferences, and motivations that inform my ability to work collaboratively?
- What are the strengths, weaknesses, preferences, and motivations that inform the ability of my colleagues to work collaboratively?

Evaluation of the ILDP at the University of North Carolina at Chapel Hill involved a collaboration among five training programs—Leadership Education in Neurodevelopmental Disorders (LEND), nutrition, pediatric dentistry, public health, and social work—in which all students participated in conventional courses and projects with interdisciplinary aspects. A subset of these students participated in ILDP workshops on interdisciplinary skills (Dodds et al., 2010). Table 30.3 shows an association between ILDP participation and the frequency of the practice of interdisciplinary skills. In other words, the intentional focus on interdisciplinary practice during the program seemed to enhance the frequency of skill use as far as 8 years afterwards. Qualitative analysis revealed the impact of the ILDP on participants' understanding of their own leadership styles and, equally as important, their abilities to appreciate the preferences and challenges of those with whom they work, which are fundamental to effective

Table 30.3. Effects of individual programs and the Interdisciplinary Leadership Development Program (ILDLP) on the frequency of interdisciplinary skill practice

Participants/Skills Frequency ^a	ILDLP	Non-ILDLP	P-value for ILDP attendance	P-value for academic program
LEND	3.41	2.87	0.008	0.048
Nutrition	3.08			
Pediatric dentistry	2.79			
M.P.H.	3.27	3.06		
M.S.W./M.S.P.H.	3.08			

Source: Margolis, Rosenberg, Umble, and Chewning (2011).

^aVery often = 5; Often = 4; Occasionally = 3; Rarely = 2; Never = 1

interdisciplinary collaboration (Margolis, Rosenberg, & Umble, 2015).

As noted, most evaluations of interdisciplinary education have been limited to the early levels of the typology described by the Kirkpatrick Model (Kirkpatrick Partners, 2018), specifically reaction, modification of attitudes/perceptions, acquisition of knowledge/skills, and behavioral change (Reeves, Boet, Zierler, & Kitto, 2015). The ILDP evaluation elicited outcomes at the change-in-organizational-practice level. Those who reported having made changes in any of the four domains of organizational practice (i.e., improve a specific program, improve the way an organization works or is structured, develop or improve a partnership, and develop a policy) reported greater mean frequencies in the use of interdisciplinary skills (Margolis et al., 2013).

From the outset, the focus of the ILDP was on understanding others rather than others' disciplines (Margolis et al., 2015). The ILDP seemed to encourage participants to develop a capacity to be curious about what motivates and underlies others' behavior and thinking and about their interests and needs rather than their specific positions when views differ (Schwarz, 2013). The ILDP curriculum, developed around a competency model, seemed to encourage a passion for interdisciplinary/interprofessional practice that may well enhance the effectiveness of the skills that participants acquired. These insights demonstrate that interdisciplinary/interprofessional training involves much more than simply taking courses in other disciplines or with students from other disciplines. The qualitative responses suggest that the ILDP played a meaningful role in the development of interdisciplinary attitudes, beliefs, and use of skills. This should alert training programs to the importance of gathering and analyzing behavioral outcomes (e.g., the frequency with which skills are used) beyond simply inquiring about the perceived value of a particular training or program.

IMPLEMENTING AND SUSTAINING INTERDISCIPLINARY EDUCATION AND PRACTICE

The growing interest in interdisciplinary education has prompted numerous efforts to define structures and processes to advance the practice (Brashers, Owen, & Haizlip, 2015; Hall & Zierler, 2015; Lawlis, Anson, & Greenfield, 2014; Menard & Varpio, 2014; National Center for Interprofessional Practice and Education, 2017; Oandasan & Reeves, 2005a, 2005b). Adapting questions posed by Oandasan and Reeves (2005b), Table 30.4 captures some of the key individual and team characteristics in planning and evaluating interdisciplinary collaborative practice initiatives. Attention to these characteristics can enhance the quality of care and begin to address the need to overcome the tendency to think in silos and to more effectively address differences in clinical opinions.

Adapting lessons from The National Academy of Sciences (NAS) report, *Facilitating Interdisciplinary Research* (National Academy of Sciences, National Academy of Engineering, & Institute of Medicine, 2005, p. 21), Table 30.5 presents a practical tool for programs to reflect on organizational characteristics necessary to advance interdisciplinary practice. Attention to such characteristics can bring a spotlight to practical challenges, such as developing the resources to support interdisciplinary efforts in, for example, care coordination, as well as to facilitate efforts to ensure that all disciplines, including self-advocates, are at the table.

The NAS describes four aspects for successful interdisciplinary research: 1) building bridges, 2) supporting the project, 3) facilities, and 4) organization/administration. Many of these conditions, meant to foster interdisciplinary research among scientists and

Table 30.4. Individual and team considerations in planning and evaluating interdisciplinary education and practice initiatives

Issues	Examples	Considerations
External/internal drivers that influence development	A clinical team makes the case for enhanced interdisciplinary training by noting the contributions of interdisciplinary practice to ongoing quality improvement, responding to the demands of health funders.	Climate of acceptance Current leadership
Potential partners	A recent occupational health graduate joins a clinical practice. After several months of participation in clinical conferences, she shares her observation that voices that could potentially contribute to the quality of care for complex cases are often not at the table. She encourages, for example, that two community organizations, known for their opportunities for families with children with special health care needs may be helpful partners.	Community organizations and individuals Family/friends of patients/clients
Opportunities within the current learning context	A physical therapist on a clinical team reaches out to the local YMCA to explore opportunities to expand its offerings for children with disabilities, such as accessible equipment and activities.	Patient population, practice sites Learner disciplines, training level, timing
Key players in designing intervention	While potential interventions often emerge from the IEP team and family, others such as siblings, extended family-members, and community-based and faith-based organizations may bring useful insights.	Degree of involvement Roles and responsibilities Communication strategies
The need to anticipate and overcome barriers	The interdisciplinary assumption that others may see things differently invites the insights and experiences of others about alternative treatment approaches in addition to potential barriers related to the IEP, based on their unique experiences.	Needs assessment, pre-evaluation
Goal of the activity at interprofessional and profession-specific levels	The members of a clinical team, working with families, share disciplinary insights as to their roles and responsibilities in working toward family-directed goals.	Defining and implementing essential elements of interdisciplinary practice
Specific objectives of activity	Team members establish a practice of regularly giving brief feedback to each other about the use of interdisciplinary skills.	Attitudes, skill development, team building to effect changes in clinical practice Quality of care and population health
Teaching methods and tools to meet objectives	Faculty regularly review literature on methods and activities to advance interdisciplinary continuing education.	Problem-based Practice-based Lab
Evaluation measures	A faculty team plans a series of workshops to introduce the principles of interdisciplinary practice to graduate students in health affairs. While the team will measure satisfaction with the workshops, they also commit to observe and measure interdisciplinary skills among the participants.	Satisfaction, learning of attitudes, knowledge, skills Behaviors that result in short and long term measurable impacts
Sustainability	Graduates of three diverse LEND programs become the directors of clinical training for their respective disciplines at a major medical center. They recognize that in order to realize the benefits of interdisciplinary training and practice, they approach center leadership with proposals and invite a conversation on strategies to raise the necessary resources.	Funding Challenging the culture

Source: Oandasan and Reeves (2005a).

engineers, are applicable to creating positive settings for interdisciplinary education and practice in other fields. For example, *building bridges* includes creating an “environment that encourages faculty/researcher collaboration”; discussing “common problems to solve”; and having “seminars to foster bridges between students, postdoctoral scholars, and investigators at the same institution” (National Academy of Sciences, National Academy of Engineering, & Institute of Medicine, 2005, p. 21).

In *Facilitating Interdisciplinary Research*, the importance of *other institutional policies* is noted. For example, tenure/promotion policies can advance training initiatives if they are recognized as valuable scholarly contributions, or they can impede such training if criteria are limited to narrow, single disciplined-based measures (Hammick, Freeth, Koppel, Reeves, & Barr, 2007).

With regard to governance, the report suggests that a matrix organization may best reflect an interdisciplinary environment. This means that faculty bring to

Table 30.5. Organizational characteristics needed to advance interdisciplinary education and practice: A reflection tool for programs

Characteristic	Definition	Examples
Physical/virtual environment	The virtual and physical environments allow collaborators from different disciplines to meet in a reasonably convenient way, either electronically or in person.	Members of an interdisciplinary group are located in offices with convenient access to one another. Expansion of the web-based clinical platform to assist communicating and sharing of appropriate documents with extended family members and community partners.
Institutional strategic plans	Missions, visions, and goals to support interdisciplinary research and teaching and community engagement	A stated priority in an organization's strategic plan is to further integrate interdisciplinary research, education, and public service. An organization's goal is that all clinicians must participate in at least one interdisciplinary continuing education offering each year.
Financial policies	Institutional financial policies make available monetary and in-kind resources to facilitate interdisciplinary collaboration.	A university policy satisfies the needs of all interdisciplinary partners to share indirect costs on grants. An institutional policy encourages departments such as developmental pediatrics, speech and language pathology, and childhood education to pool financial resources to provide joint training programs.
Other institutional policies	Institutional policies other than financial policies facilitate and support interdisciplinary collaboration.	The dean of a school of nursing promotes a policy to encourage that articles written with colleagues from other disciplines are valued in evaluation for promotion. An occupational therapist paves the way for a physical therapy graduate student to satisfy clinical education requirements related to adaptive equipment use.
Scheduling	A shared calendar that facilitates collaboration across institutional units (e.g., academic programs or departments).	Discipline-specific departments have a common calendar that allows designated blocks of time to be set aside for interdisciplinary education and meetings. A pediatric residency program sets aside a designated block of time for exchange between disciplines (e.g., a journal club).
Governance	Multiple stakeholders, including professionals, clients, families, and/or community members, are active participants in setting the direction of interdisciplinary activities.	The program includes all relevant stakeholder groups on a steering/advisory committee. Family representatives are involved in the revision of clinical and non-clinical curriculum through activities such as completing surveys, participating in planning meetings, and providing ongoing feedback.
Institutional leadership	Relevant institutional leaders, such as deans, chairs, provosts, and clinical program directors acknowledge and support an overall strategic goal of interdisciplinary education, research, and collaboration among schools, departments, and programs.	The chair of a special education department intentionally hires faculty from disciplines such as public health, not normally represented in the department. A dean from a school of medicine supports a partnership with the university's school of public health to offer students dual-degree options between schools.
Champions	Individuals who advocate for, initiate, and maintain clinical or programmatic interdisciplinary collaborations.	A faculty member from a special needs nutrition program initiates a multischool collaborative group to develop an interdisciplinary leadership curriculum. She encourages other faculty to engage in similar initiatives. A psychologist holds a program accountable to ensure that all necessary disciplines are represented on clinical assessment teams.
Culture of collaboration	A culture of interdisciplinary collaboration exists when it is the norm for professionals from different disciplines to value working together. Responsibility is shared in reaching goals, making joint decisions, resolving conflicts, and developing and implementing activities. Trust and respect make it possible to share responsibility in reaching goals.	In response to a community funding opportunity, one of the first questions a clinician asks is, "How will I involve my colleagues from other disciplines?" When facing complex family situations, professionals feel comfortable turning to colleagues in other disciplines to provide different perspectives on the situations.
Accountability	Program leaders routinely evaluate whether the programmatic structure, function, and outcomes are consistent with interdisciplinary practice.	In the annual review of a clinical team member, a department head solicits a report about interdisciplinary activities. Clinicians routinely review reports to ensure that the information provided to clients (individuals and caregivers) reflects an interdisciplinary family-centered interpretation of clinical assessments and suggestions for intervention.

(continued)

Table 30.5. (continued)

Characteristic	Definition	Examples
Interdisciplinary curricula and instructional methods	Curricular content and instructional objectives are designed to create interdisciplinary thinking and practice among students or trainees. The structure of the training program may include collaborative efforts among disciplines such as joint degrees, courses jointly sponsored and taught, or team teaching by colleagues from varied disciplines.	A program offers an interdisciplinary leadership certificate that includes courses and learning experiences that reflect multiple disciplines. Interdisciplinary clinical teams are used as a teaching forum to advance interdisciplinary knowledge and skills.
Research initiatives and publications	Interdisciplinary research projects and publications integrate the perspectives of investigators from multiple disciplines.	A social work faculty member and a maternal and child health faculty member co-author an article on the role of Title V in domestic violence prevention. A multidisciplinary team authors a paper related to the assessment of children with rare genetic disorders.

the table their different skills or disciplines to focus on collaborating such that their shared expertise can facilitate interdisciplinary training in contrast to enhancing the development of their particular skills in trainees.

In addition, the role of a *culture of collaboration*, a receptive interpersonal and institutional environment where the norms support interdisciplinary efforts, seems more often implicit than explicit in the literature. Commitment to a process of *accountability* is key. *Facilitating Interdisciplinary Research* notes that there should be rewards for academic leaders who encourage interdisciplinary training as well as professional recognition. On the level of programs, there needs to be an explicit effort to articulate goals, review progress, and make changes as indicated, as well as a commitment to accountability across programs and institutions (McHugh, Margolis, Rosenberg, & Humphreys, 2016).

As emphasized by Reeves and colleagues (2015) and the Institute of Medicine (2015), there is an extensive literature on the effects of interdisciplinary training. There are, however, relatively few studies that speak to outcomes; that is, the effects of interdisciplinary care on service delivery and/or patient care. Many studies focus on the development of perceptions and attitudes; knowledge and skills; and, to some degree, behaviors. Table 30.5 suggests that many characteristics of a program or institution must be aligned and addressed. Similarly, at the team level, interactions and meetings about clinical matters should be intentionally attentive to the elements of meaningful interdisciplinary practice.

SUMMARY

- The complex interactions among many systems demand an understanding of interdisciplinary

attitudes and a commitment to the skills and competencies that reflect interdisciplinary practice.

- This understanding and commitment build on a valuable and insightful foundation expressed over the years in federal and state policy, programmatic practices, and educational initiatives.
- In spite of the longstanding engagement by families, clinicians, researchers, and policy makers, there must be investment in ongoing efforts to define and evaluate the impact of interdisciplinary education and practice.
- To reach the goals of interdisciplinary practice, the many faculty, programs, and organizations that touch the lives of these children and their families should reflect intentionally on interdisciplinary principles and characteristics as they seek to implement this type of practice.

CHAPTER 31

Early Intervention Services

Toby M. Long

Upon completion of this chapter, the reader will

- Describe the rationale for and history of early intervention services
- Explain the principles of early intervention
- Describe the programs and supports available for young children receiving early intervention services and their families
- Identify the components of federal legislation that support those receiving early intervention services

The availability of **early intervention (EI)** services in virtually every community in the United States shows society's commitment to supporting infants and toddlers with developmental disabilities and their families. EI services are usually provided in the context of federal legislation that defines the structural components and principles governing state-based services for infants and toddlers (from birth to 3 years of age) with disabilities. Services and supports available include **habilitation** therapies, family counseling, early childhood educational services, and others as determined by a **multidisciplinary** team in collaboration with the child's family. This array of services is provided in many settings, in collaboration with a variety of agencies, and utilizes various models of service delivery.

■ ■ ■ CASE STUDY

Carl is a 6-month-old boy who was born at a gestational age of 26 weeks. After a difficult 4-month hospitalization

in the neonatal intensive care unit, he was discharged to his home. **Neurodevelopmental assessment** just prior to discharge showed that his cognitive function was at a newborn level and he had markedly increased tone in his legs. Based on these significant developmental delays/abnormalities, he was referred by his neonatologist to the local EI program. After a comprehensive, multidisciplinary evaluation, he was determined to be eligible for services. An individualized family service plan (IFSP) was then developed. Carl was provided weekly home visits by a physical therapist (for increased tone) and speech-language therapist (for feeding problems). These therapies were also provided at his child care center on a weekly basis. In addition, each provider arranged a home visit with Carl's parents once a month so that they could discuss family concerns and priorities. As a result of the support provided through these interactions, Carl's parents are feeling increasingly confident and competent in caring for him and in supporting his development.

Thought Questions:

How does the primary service provider model of service delivery support the principles of EI? How can EI team members use the description of participation to guide the development of the IFSP?

PRINCIPLES OF EARLY INTERVENTION

The primary goals of EI are to enhance the development of infants and toddlers and minimize the potential for developmental delay by supporting the family to promote their child's optimal development and facilitate the child's participation in family and community activities, (Dunst, Bruder, & Espe-Scherwindt, 2014; Workgroup on Principles and Practices in Natural Environments, 2008). Within those goals, EI focuses on encouraging active participation of families in the intervention by embedding strategies into everyday activities and routines and by delivering services in a manner that is

- Family centered and culturally and linguistically competent;
- Developmentally supportive, strengths based, and helpful for promoting children's participation in their natural environments;
- Comprehensive, coordinated, and team based;
- Individualized, flexible, and responsive to the changing needs of young children and families; and
- Based on the highest quality evidence available.

RESEARCH SUPPORT FOR THE VALUE OF EARLY INTERVENTION

Research over the last 30 years indicates that intervention during early childhood achieves immediate and sustained developmental benefits (Center on the Developing Child at Harvard University, 2010; Spittle, Orton, Anderson, Boyd, & Doyle, 2015). These benefits have also been shown to save money for the community and family over time (Heckman, 2012; also see the textbox on what Heckman has contributed to the evidence in support of EI). Much scientific evidence demonstrates that EI programs generate important benefits for both young children at risk for disability and for those with established disabilities (Dunst et al., 2014; Early Childhood Technical Assistance Center, 2018a). Numerous studies also have identified that a decline in development can be prevented or at least mitigated through providing comprehensive EI programs (Spittle et al., 2015). However, individual responsiveness to EI varies depending on a

variety of biological, social, and environmental issues. Consistent evidence for long-term benefits is limited. Current research, in addition to determining the effectiveness of early childhood interventions, focuses on determining which program elements are most effective for which children and under what circumstances. Research also investigates how programs can produce the greatest benefits at the lowest cost.

Return on Investment of EI

James Heckman, a Nobel Prize-winning economist, has demonstrated that high-quality early childhood programs for vulnerable or disadvantaged children can deliver a 13% return on investment (see heckmanequation.org to learn more).

PREVALENCE AND EPIDEMIOLOGY

The Individuals with Disabilities Education Improvement Act (IDEA) of 2004 (PL 108-446) Part C program (Early Intervention Program for Infants and Toddlers with Disabilities) mandates coordinated, multidisciplinary, and interagency systems to deliver specialized EI services, early childhood special education (ECSE), or special education (SE) to all eligible children from birth up to 3 years of age displaying cognitive, behavioral, and/or physical developmental delays or disabilities. In 2015, 357,715 children from birth up to 3 years of age received EI services through Part C of IDEA (3% of the population of children in this age range; U.S. Department of Education, 2017). Children receiving Part C services include those with developmental delays and those with diagnosed conditions.

Overall, approximately 64% of children eligible for Part C services have a developmental delay, 20% have a diagnosed medical condition, and 16% have biomedical and/or environmental risk factors (Hebbeler, Mallik, & Taylor, 2010). In addition, 43% of children receiving services live in households with incomes less than \$25,000 a year (Hebbeler et al., 2010). Given the well-established association between disadvantaged status and disability (Ekono, Yang, & Smith, 2016), the system's ability to enroll large numbers of these families is commendable.

COMPONENTS OF PART C OF IDEA: THE INFANTS AND TODDLERS WITH DISABILITIES PROGRAM

Based on research indicating that services provided to young children could prevent or ameliorate biological, social, and environmental risks on development (Spittle et al., 2015), the 1986 amendments to IDEA

(then called the Education of the Handicapped Children Act, PL 99-457) established the Infants and Toddlers Program, or EI System. From its inception, this part of the law was meant to be a system of cooperation and collaboration across child-serving systems to provide comprehensive services and supports to families with infants and toddlers with disabilities or delays. The purposes of the Infants and Toddlers Program, or Part C of IDEA, are stated in the supporting legislation as follows:

1. To enhance the development of infants and toddlers with disabilities, to minimize their potential for developmental delay, and to recognize the significant brain development that occurs during a child's first 3 years of life
2. To reduce the educational costs to society, including our nation's schools, by minimizing the need for SE and related services after infants and toddlers with disabilities reach school age
3. To maximize the potential for individuals with disabilities to live independently in society
4. To enhance the capacity of families to meet the special needs of their infants and toddlers with disabilities
5. To enhance the capacity of States and local agencies and service providers to identify, evaluate, and meet the needs of all children, particularly minority, low-income, inner city, and rural children, and infants and toddlers in foster care

Each state must create a system that includes 16 components (see the textbox titled **IDEA: Minimum Components of a Statewide, Comprehensive System of Early Intervention Services to Infants and Toddlers with Special Needs**). States are required to ensure that those individuals providing the services are appropriately qualified and that a central directory of providers, services, and agencies is available to help identify resources of all kinds relevant to EI. Other structural components are administrative in nature, addressing interagency cooperation, reimbursement, and procedural safeguards. In addition to policies that regulate procedures, financing, and professional standards, five components are specific to providing services: 1) identification and referral, 2) determination of eligibility, 3) development of an IFSP, 4) provision of services, and 5) transition from EI services at age 3. In addition, states are required to report the percentage of infants and toddlers with IFSPs who demonstrate improvement in three outcome areas: social-emotional skills, acquisition and use of knowledge and skills, and the ability to take appropriate action to meet needs.

IDEA: Minimum Components of a Statewide, Comprehensive System of Early Intervention Services to Infants and Toddlers with Special Needs

1. A rigorous definition of the term *developmental delay*
2. Appropriate EI services based on scientifically based research that are, to a practical extent, available to all infants and toddlers with disabilities and their families, including Native American and homeless infants and toddlers
3. Timely and comprehensive multidisciplinary evaluation of the needs of children and family-directed identification of the needs of each family
4. IFSP and service coordination
5. A comprehensive Child Find and referral system
6. A public awareness program, including the preparation and dissemination of information to be given to parents
7. A central directory of services, resources, and research and demonstration projects
8. A comprehensive system of personnel development, including the training of paraprofessionals and primary referral sources
9. Policies and procedures that ensure that personnel are appropriately and adequately prepared and trained
10. A single line of authority in a lead agency designated or established by the governor
11. A policy pertaining to contracting or otherwise arranging for services
12. A procedure for securing timely reimbursement of funds
13. Procedural safeguards
14. A system for compiling data on the EI system
15. A state interagency coordinating council
16. Policies and procedures to ensure that to the maximum extent appropriate, EI services are provided in natural environments except when EI cannot be achieved satisfactorily in a natural environment

Identification and Referral

Under Part C regulations of IDEA (PL 108-446), states are required to establish programs for finding and

identifying infants and toddlers who may qualify for EI. These programs and procedures are referred to as Child Find (<http://ectacenter.org/topics/earlyid/idoverview.asp>). Child Find efforts are most effective when coordinated with other EI programs, such as Medicaid's early and periodic screening, diagnosis, and treatment program. Primary care providers are in a key position to identify young children who are at risk for or who have developmental delays or disabilities (Adams, Tapia, & Council on Children with Disabilities, 2013).

Developmental screening is often the first step in identifying and referring infants and toddlers who could benefit from EI services. When developmental screening occurs in the context of a well-child medical visit, it reinforces the concept that health and development are interrelated. Responding to parental concerns about a child's development has been shown to be as effective in identifying developmental delay as professional opinion and/or standardized screening (Council on Children with Disabilities, Section on Developmental Behavioral Pediatrics, Bright Futures Steering Committee, & Medical Home Initiatives for Children with Special Needs Project Advisory Committee, 2006; Woolfenden et al., 2014). An infant or toddler can be referred to the local EI program directly by anyone (including a relative or friend) who suspects that the child has a developmental delay or disability. Best practice supports referrals to local EI programs that come from parents following discussions with their primary health care providers or from the primary health care provider (Adams et al., 2013). Developmental screening is another option that a state may choose to include as part of its comprehensive Child Find system (IDEA 2004). It should involve the family and other sources of information using a process that is culturally and linguistically sensitive. It should be reliable, valid, cost effective, and time efficient. It should be seen not only as a means of early identification, but also as a service that helps the family understand the child's developmental progress. Several developmental screening tests are commercially available, including 1) the Ages & Stages Questionnaires®, Third Edition (ASQ-3®; Squires & Bricker, 2009); 2) the Denver II (Frankenburg et al., 1992); and 3) the Parents' Evaluations of Developmental Status (Glascoe, 1997).

Determining Eligibility for Early Intervention Services

According to IDEA, each state is required to define criteria by which a child is eligible to receive EI services under Part C. Of note, infants and toddlers who do not meet the eligibility criteria for services under the state-run Part C program can still receive services through

other systems, such as directly at a clinic or through a private practitioner.

Current federal regulations describe three categories of eligibility: 1) The child demonstrates a measurable **developmental delay** as defined by each state; 2) the child has a diagnosed physical or mental condition that has a high probability of resulting in developmental delay (e.g., a child with Down syndrome); or 3) professionals who are conducting the evaluation determine that a child demonstrates behaviors indicating atypical development (e.g., a child suspected to have autism) and could benefit from EI services and supports, a process referred to as informed clinical opinion. IDEA indicates that a child meets the definition of developmental delay if he or she has a measurable delay in one or more of five areas: cognitive, physical, communication, social or emotional, and/or adaptive skills. Each state, however, decides how to define the term *measurable delay*. State-specific eligibility criteria can be found online at http://ectacenter.org/~pdfs/topics/earlyid/partc_elig_table.pdf.

A multidisciplinary team, defined by IDEA (34 CFR §303.24) as the involvement of two or more separate disciplines or professions, conducts the eligibility evaluation to determine if a child meets the state-specified eligibility criteria. The process often begins when the family first calls the infant and toddler program for assistance. The program then performs four activities: coordination of a multidisciplinary eligibility evaluation, assessment, development of the IFSP, and commencement of appropriate EI services. These activities must be completed within 45 calendar days from the date that the family provides consent to the initial screening, evaluation, or assessment (§303.310 [b, 2]). After a family is referred, a service coordinator is assigned to partner with the family to plan and coordinate all of the steps leading to the development of a service plan, if appropriate. If the child is found to be eligible, the service coordinator will 1) continue to assist the family in coordinating services across agency lines; 2) serve as the single contact for parents/families to obtain needed help and services; 3) assist families in gaining access to services identified in the IFSP; and 4) help the family through the process of transition to preschool, school, or other appropriate services or exiting the program.

The eligibility evaluation process must be timely, comprehensive, and multidisciplinary. Pertinent records relating to the child's current health status as well as medical history must be reviewed. The evaluation includes assessing the child in five areas of development: physical (including vision, hearing, and gross and fine motor development), cognitive, communication, social-emotional, and adaptive. The multidisciplinary evaluation team must include 1) a family member and

2) two professionals representing different disciplines or one individual who is qualified in more than one discipline or profession (§303.24). For example, the professionals might include an early childhood special educator and a speech-language pathologist or perhaps a motor therapist such as an occupational therapist or a physical therapist. The process must reflect the unique strengths and needs of the child. In addition, family members provide information about concerns, priorities, and resources that may affect their child. (See Box 31.1 on the role that families play on the team.)

In the case study at the beginning of this chapter, Carl was determined to be eligible for EI following his evaluation by a physical therapist and special educator. The assessment indicated that Carl met the specified amount of delay for the state in which he resides in the motor area and in his adaptive skills. In addition, at the time of the evaluation he continued to demonstrate hypertonia in both his legs. The eligibility team also gathered information from the family using a routines-based interview process. All this information was used to develop Carl's IFSP.

Early Intervention Services

Assistive Technology Devices and Services

Audiology

Family training

Health services

Medical services (for diagnostic or evaluation purposes only)

Speech and language pathology

Physical therapy

Occupational therapy

Psychological services

Service coordination

Social work services

Special instruction (also referred to as developmental therapy)

Transportation and related costs

Vision services

Other services as determined by IFSP team

Development of an Individualized Family Service Plan

If the child is found eligible for services through the multidisciplinary child and family evaluation process, a multidisciplinary team, including the parents, develops an IFSP, ensuring that the required services are identified and coordinated and that they relate to the outcomes decided by the team. (See the Early Intervention Services textbox for a list of the services available through Part C). The IFSP can also identify other services if needed to meet the outcomes identified in the IFSP (§303.13 [d]). These services must be provided in natural environments to the maximum extent appropriate to meet the needs of the child. Natural environments are defined in federal regulations as “settings that are natural or normal for an infant or toddler without a disability, and may include the home” (Sec. 303.26). Natural environments are not limited to the home or any other specific place, but they should include activities and routines that offer naturally occurring learning opportunities (Dunst et al., 2014; Law, Darrah, & Pollack, 2011a, 2011b). IDEA describes eight required elements of the IFSP (see the Required Elements of an Individualized Family Service Plan textbox).

Required Elements of an Individualized Family Service Plan

1. A statement of the infant's or toddler's present levels of physical development, cognitive development, communication development, social or emotional development, and adaptive development based on objective criteria

BOX 31.1 INTERDISCIPLINARY CARE

Families Are Critical Team Members

As a member of the multidisciplinary team, the family contributes to the evaluation and assessment process by discussing their concerns for their child, their priorities, and the resources they have available that they find supportive. This information is used to formulate outcomes and identify services and supports that are responsive to the family's needs.

2. A statement of the family's resources, priorities, and concerns relating to enhancing the development of the family's infant or toddler with a disability
3. A statement of the major outcomes expected to be achieved for the infant or toddler and the family, as well as the criteria, procedures, and timelines used to determine the degree to which progress toward achieving the outcomes is being made and whether modifications or revisions of the outcomes or services are necessary
4. A statement of specific EI services necessary to meet the unique needs of the infant or toddler and the family, including the frequency, intensity, and method of delivering services
5. A statement of the natural environments in which EI services should be appropriately provided, including a justification of the extent, if any, to which the services will not be provided in a natural environment
6. The projected dates for initiation of services and the anticipated duration of the services
7. The identification of a service coordinator from the professionals most immediately relevant to the infant's or toddler's or family's needs (or who is otherwise qualified to carry out all applicable responsibilities) who will be responsible for the implementation of the plan and coordination with other agencies and persons
8. The steps to be taken to support the transition of the toddler with a disability to preschool or other appropriate services

Service Provision

According to the mission statement within the statement paper "Agreed Upon Mission and Key Principles for Providing Early Intervention Services in Natural Environments," "Part C early intervention builds upon and provides supports and resources to assist family members and caregivers to enhance children's learning and development through everyday learning opportunities" (Workgroup on Principles and Practices in Natural Environments, 2008, p. 2). This mission is based on seven key principles that underpin family-centered services and supports (see the textbox titled Key Principles for Providing Early Intervention Services in Natural Environments) and that act as guidelines on how EI services should be provided.

Key Principles for Providing Early Intervention Services in Natural Environments

1. Infants and toddlers learn best through everyday experiences and interactions with familiar people in familiar contexts.
2. All families, with the necessary supports and resources, can enhance their children's learning and development.
3. The primary role of a service provider in early intervention is to work with and support family members and caregivers in children's lives.
4. The early intervention process, from initial contacts through transition, must be dynamic and individualized to reflect the child's and family members' preferences, learning styles, and cultural beliefs.
5. IFSP outcomes must be functional and based on children's and families' needs and family-identified priorities.
6. The family's priorities, needs, and interests are addressed most appropriately by a primary provider who represents and receives team and community support.
7. Interventions with young children and family members must be based on explicit principles, validated practices, best available research, and relevant laws and regulations.

Reprinted from Workgroup on Principles and Practices in Natural Environments, OSEP TA Community of Practice: Part C Settings. (2008, March). *Agreed upon mission and key principles for providing early intervention services in natural environments*. Retrieved from http://ectacenter.org/~pdfs/topics/families/Finalmissionand-principles3_11_08.pdf; reprinted by permission.

The principles of EI promote a flexible system of service provision developed to respond to the team-based outcomes and not just to the diagnosis or the child's level of delay. Contemporary practice models that encompass the principles described above as well as those defined by the Division of Early Childhood Recommended Practices (www.dec-sped.org/dec-recommended-practices) include routines-based intervention (McWilliam, 2016), activity-based intervention (Pretti-Frontczak & Bricker, 2004; Valvano, 2004), context-based learning opportunities (Law et al., 2011b), and participation-based services

(Campbell & Sawyer, 2007). These models all support the following:

1. The critical roles of families as teachers of their children and practitioners as facilitators and teachers of both families and their children (Boyer & Thompson, 2014)
2. The use of common activities and routines as contexts for children's learning (Chai, Zhang, & Bisberg, 2006; Stremel & Campbell, 2007)
3. The need for practice and repetition in order for learning to occur (Ulrich, 2010)

To be successful these models all require that meaningful outcomes be identified and that EI professionals provide a spectrum of consultative and direct services. This approach often departs from the traditional discipline-specific model of a set frequency per week. Meaningful outcomes go beyond specific disciplinary goals to effectively address the child's participation in family and community activities and routines.

Different types of services as well as levels of service may be needed depending on the number of caregivers (e.g., parents, grandparents, and child care providers) and the learning contexts. On the one hand, a biweekly visit with a parent and child who spend the day together at home may suffice to accomplish the desired outcome. On the other hand, a multiple-caregiver situation often requires more frequent contact to demonstrate strategies and allow for more collaboration with key adults. A flexible model might emphasize sequential rather than simultaneous services or varying levels of intensity or frequency. For example, it may be beneficial to "front-load" services, increasing the frequency of services initially and then gradually decreasing them to weekly. Services relate to the accomplishment of the outcome. Each outcome should have distinct services, frequency, intensity, and location identified prior to the implementation of the IFSP. Shifting to a flexible, outcomes-guided model that is family directed increases the likelihood that the recommendations for services will emerge from a thorough analysis of child and family priorities. This individualized, outcomes-driven model contrasts with the traditional model of providing a predetermined group of services by specific disciplines that are driven by a particular disability rather than by the specific needs, priorities, and concerns of the family (Colyvas, Sawyer, & Campbell, 2010; Sheldon & Rush, 2013).

Currently, many state EI programs are implementing a primary service provider (PSP) model. The PSP model promotes assigning one team member to

primarily interact with the child, the child's family, and other caregivers (Sheldon & Rush, 2013). The PSP provides EI services for the child and family with consultation, support, and or coaching from other team members. Any member of the IFSP team can be a PSP. Once the outcomes are determined, the team will decide which member of the team would best serve the family as the PSP. Rush and Sheldon (2012) recommend that teams consider the characteristics of the parent/family, child, environment, and practitioner when deciding on which team member would be the PSP. As an example, physical therapists are often considered as the PSPs for children with a primary motor disability or delay. However, it is critical that whoever is the PSP should have the knowledge and skills to collaborate with other providers in developing comprehensive, integrated intervention sessions.

Contemporary Practice Models

Contemporary practice models support intervention in a natural environment by stressing the critical roles of the family as the child's teacher and the EI provider as the family's educator. Traditional service delivery is child focused; families often simply observe the service, or the professional teaches the family to execute a specific strategy (Peterson, Luze, Eshbaugh, Jeon, & Kantz, 2007). Intervention strategies that assist families and other caregivers to promote the child's development within the context of naturally occurring learning opportunities are consistent with the concept of natural environments and the intent of family-centered EI (Boyer & Thompson, 2014; Bruder, 2000; Peterson et al., 2007).

By focusing intervention on activities and routines that individual families participate in rather than on locations, the provider takes advantage of natural learning opportunities and family interactions, preferences, and resources. In this participation-based approach, EI professionals intervene with a child by teaching caregivers how to use two primary types of child interventions to promote the child's participation and learning: 1) adapting the environment, materials, or the activity/routine, including the use of assistive technology, and 2) embedding individualized learning strategies within family routines (Colyvas et al., 2010).

Other strategies, such as activity-based interventions (Pretti-Frontczak & Bricker, 2004; Valvano & Rapport, 2006), emphasize that although the intervention is within an activity, routine, or context, the *target* of intervention is the child, promoting his or her skill development. Routines-based intervention stresses the

importance of engagement, independence, and social relationships within a naturally occurring child activity (McWilliam, 2010). Because intervention with infants and toddlers is a collaborative process, often including multiple caregivers, caregiver satisfaction or dissatisfaction is also considered. Caregivers must indicate dissatisfaction with the child's performance if they are going to identify functional outcomes from which they can make adaptations or embed a learning strategy. Dunst (2007) promotes the use of contextually mediated practices as an approach to promote the child's acquisition of new skills, competence, and knowledge. Contextually mediated practices use everyday family and community activities (natural environments) as the sources or "context" for learning (see Box 31.2 for more information on contemporary EI).

Transition from Early Intervention Services

Transition is a process that children and families experience as they move from one program or setting to another. Families of young children with developmental delays and disabilities may need to move between home and hospital or from EI to preschool. Under IDEA, young children are no longer eligible to receive EI services at age 3. Thus, the Part C system must begin, if needed, to transition the child from the Part C system at about 2 years, 6 months, to ECSE services, inclusive preschool or childcare programs, or other appropriate services. The 39th Report to Congress on the implementation of IDEA indicates that 60.3% of children exiting Part C were eligible to receive Part B, 619 services during 2014–2015 (U.S. Department of Education, 2017). Careful planning and preparation can ensure that change occurs in a timely and effective manner. Transition planning may also help to alleviate parental stress. To ensure a seamless move from EI to other appropriate services and supports, the IFSP must include a transition plan.

In the case study, Carl received EI services from a physical therapist, receiving intermittent consultation and support from a speech-language pathologist and occupational therapist as needed. As Carl was approaching his third the team began the process of transitioning Carl out of Part C services. By this time, he had received a diagnosis of spastic diplegic cerebral palsy and was using a reverse walker to support his mobility. As his expressive language abilities were not as well developed as his receptive skills, he started using a simple communication device when he was about 2 years of age. Carl was determined to be eligible to receive SE and related services through the Part B 619 program from his local school system. It was planned that starting at age 3 he will attend a school-based Head Start program in his community. His team, consisting of SE, physical therapy, and speech-language pathology professionals, will consult with the classroom teacher on a regular basis, helping the teacher to adapt, accommodate, and or modify her lesson plans as needed to ensure that Carl participates fully in all learning opportunities.

OUTCOMES

It has now been more than 30 years since the establishment of a formal EI system in the United States. Judged by usual standards, this program has been successful. All 50 states and jurisdictions are participating in Part C, meaning that each of the required structural components is in place. Moreover, the number of children served continues to grow annually.

The Department of Education instituted the Early Childhood Outcome system to measure and document outcomes of children and families receiving Part C services. Each state is required to report on the percent of infants and toddlers with IFSPs who demonstrate improved 1) positive social-emotional skills (including social relationships), 2) acquisition and use of knowledge

BOX 31.2 EVIDENCE-BASED PRACTICE

Contemporary Early Intervention

Professionals who provide services to infants and toddlers believe that early childhood intervention positively effects development, health, and family well-being. These positive effects have been documented for decades. Contemporary early childhood intervention builds on this evidence that indicates the following:

- Supportive relationships, adaptive skill building, and positive experiences help young children develop resilience.
- Building the capabilities of adult caregivers helps strengthen the relationships essential to children's lifelong learning, health, and behavior.
- The most important influence on early brain development is the positive interaction between young children and caring adults.

and skills (including early language/communication and early literacy), and 3) use of appropriate behaviors to meet their needs. States are also required to report on the percentage of families participating in Part C who report that EI services have helped their family know their rights, effectively communicate their children's needs, and help their children develop and learn.

Children who exit the system at age 3 are showing clear gains in development. Fifty-nine percent of the children exit with age-appropriate social interaction skills; 50% have age-appropriate skills in knowledge and developmental skills; and 57% use age-appropriate actions to meet their needs (Center for IDEA Early Childhood Data Systems, 2017). The family data also indicate that the Part C system is helpful: Over 89% of families receiving Part C services indicate knowing their rights, 90% report being able to effectively communicate their needs, and over 92% feel confident in helping their child develop and learn (Early Childhood Technical Assistance Center, 2018b).

Although the Part C program is serving many children, states continue to narrow the eligibility criteria (IDEA Infants and Toddlers Coordinators Association, 2017), and children with milder disabilities and less significant delays may actually be the ones who benefit the most from EI services for which they may no longer be eligible to receive (Hebbeler et al., 2010). In addition, evidence exists to suggest that children are receiving fewer services and supports to meet IFSP outcomes (Hebbeler et al., 2010). Although a 2010 study indicated that 63% of the families received an average of 6.5 hours per month of EI services, the 2017 survey of Part C State Coordinators indicates that the average service hours has decreased to about 4 hours per month.

Taken together, it is evident that a comprehensive EI system composed of well-defined structural components can be found in states and communities throughout the United States, providing services and supports to infants and toddlers and their families. However, it is recognized that such a complex and evolving system can be substantially improved to more effectively and efficiently meet the needs of children and families (Boavida, Aguiar, & McWilliam, 2014; Boyer & Thompson, 2014; Dunst, 2007; Tomasello, Manning, & Dulmus, 2010).

SUMMARY

- EI services for infants and toddlers with disabilities or developmental delay are available in all states and territories.
- Following a multidisciplinary team evaluation to determine eligibility for services, an IFSP is developed.

- Outcomes on the IFSP are created to promote participation in family and community routines
- Services are provided in the natural environment.
- More states are adopting the primary service provider system of service provision.
- Research on the effectiveness of EI has demonstrated the potential for achieving important benefits for infants, toddlers, and their families.

CHAPTER 32

Rehabilitative Services

Melissa Fleming, Marisa Birkmeier, Mackenzie Brown,
Justin M. Burton, Satvika Garg, and Sarah H. Evans

Upon completion of this chapter, the reader will

- Describe the importance and components of a comprehensive functional assessment in children with developmental disabilities
- Explain the roles of various therapists and pediatric subspecialists involved in the rehabilitative care of children with disabilities
- Identify unique physical and functional treatment approaches to common diagnoses, including cerebral palsy, muscular dystrophy, and spina bifida
- Distinguish diagnosis-specific clinical features that guide physical and functional treatment approaches
- Recognize the variable physical and functional treatment modalities and interventions available to treat children with disabilities
- Identify precautions to consider when providing rehabilitative services to children with these specific diagnoses

The overall goal of treatment for children with physical disabilities is to optimize functional independence with completion of age-appropriate tasks. Individual plans of care should be patient and family centered. In order to achieve this goal, rehabilitation teams use the World Health Organization's International Classification of Functioning, Disability, and Health (ICF) framework for defining health and disability (Figure 32.1). The ICF conceptualizes the unique challenges that children with physical disabilities face, providing practitioners with a framework to develop a comprehensive treatment approach to address the barriers to physical, psychosocial, and emotional health (World Health Organization, 2007).

Interventions used to achieve the goal of functional independence are varied and range from providing durable medical equipment to prescribing medication. Equipment and bracing are used to maximize independence in the least restrictive and most functional manner possible. Pharmaceuticals focus on decreasing symptoms that may be limiting the child's voluntary movements, thereby improving his or her participation in daily care activities.

Most children with physical disabilities will engage in occupational, physical, and/or speech therapy at some point in their development. These specialists provide a supportive and educational environment to optimize developmental goals and improve functional

Figure 32.1. The ICF model. A health condition (disease or disorder) exists because of physiologic disturbances at a cellular, molecular, or tissue level. These physiological disturbances cause changes in body function and structure, which can result in an individual experiencing disability (activity restrictions), causing difficulties functioning in societal settings (participation restrictions). Environmental and personal factors further influence and provide a context for changes and differences in function. For example, a 5-year-old boy with joint contractures related to cerebral palsy will have difficulties with mobility and restricted play, which will manifest in specific ways in his particular home, neighborhood, and school. (Adapted from the World Health Organization. [2013]. *International Classification of Functioning, Disability and Health [ICF]: ICF and ICF-Online*. Retrieved from <http://apps.who.int/classifications/icfbrowser/>)

performance. Within all three therapies, there exists a vast spectrum of techniques and approaches that can vary widely in response to the specific needs of the child and considerations of any related health conditions.

This chapter describes an approach to the assessment of children with physical disabilities, followed by a description of physical and functional treatment approaches for children with commonly encountered diagnoses causing physical disability, focusing on cerebral palsy, muscular dystrophy, and spina bifida. The unique clinical features of each condition that merit a specialized rehabilitative treatment approach are identified, as well as specific precautions and considerations when working with these children.

PRINCIPLES AND PROCESSES OF FUNCTIONAL ASSESSMENT

The clinical assessment, which includes a patient history and physical examination, is the initial component of every patient encounter because it guides diagnosis and treatment. The assessment of children with physical disabilities varies based on both age and developmental skills, which often do not match. Clinicians

begin addressing this challenge by gathering a history regarding the child's developmental progress and skills. They also perform a physical examination to evaluate the efficiency with which the child is able to complete these skills and to identify any barriers to progress. Overall, the clinical assessment identifies the child's functional strengths and weaknesses in his or her interactions at home and within the community so that the team of clinicians can optimize the child's participation in society.

A comprehensive assessment considers the child and family as a whole. The ICF, noted above, provides clinicians with a useful framework for conceptualizing the child's level of health and function. It consists of five interacting components: 1) health condition, 2) ability to participate in daily living, 3) required activities, 4) body functions and structures, and 5) environmental and personal factors (World Health Organization, 2013; Table 32.1). The ICF can be very helpful in delineating impairments that limit function, leading the provider to consider appropriate interventions.

In evaluating a child with physical disabilities, the first step is to assess the child's health condition or disease that is the cause of an impairment in function. Examples of impairments include weakness,

Table 32.1. Examples of the World Health Organization's *International Classification of Functioning, Disability, and Health (ICF)* model (2007)

Health condition	Impairments	Activity restrictions	Participation restrictions
Cerebral palsy	Hypertonia	Impaired fine motor skills	Need adaptive driving setup
Duchenne muscular dystrophy	Weakness	Difficulty walking/impaired mobility	Difficulty accessing home and school
Stroke	Hemi-neglect	Impaired navigation around obstacles	Need for supervision and assistance in the community
Burn	Pain and contractures	Limited arm movement	Need for clothing modifications
Pilocytic astrocytoma brain tumor	Hearing impairment	Limited communication	Risk for social isolation and learning issues in school

hypertonia, sensory deficits, contractures, vision and hearing loss, pain, and anxiety. Impairments can lead to “activity restriction,” or disability, and to “participation restrictions,” or handicaps. Members of the rehabilitation team often use the ICF model to conceptualize how the child’s health condition is affecting his or her body and resultant lack of functional independence.

The child with physical disabilities is best treated by an interdisciplinary team of clinicians, a topic that is explored in detail in Chapter 30. The rehabilitation team focuses on specific elements of the child’s history

and physical development to develop a functional assessment. These are described within the sections that follow.

After assessing the child and determining what impairments are impacting function, the rehabilitation team works with the family (a critical partnership) to develop attainable functional goals and devise a plan to work toward those goals (Table 32.2). Elements of the medical history obtained from the child and family can facilitate diagnosis and lead to the appropriate interventions.

Table 32.2. Medical history

Element of history	Key information	Example questions	Implications
Prenatal and perinatal history	Gestational age at birth, complications during pregnancy or at birth, length of neonatal intensive care unit stay if required, need for perinatal/neonatal surgeries or procedures	Was the child born prematurely? Did the child require a hospital admission after birth?	Prematurity can affect neurodevelopment. Prematurity is a major risk factor for cerebral palsy. Many congenital conditions, such as spina bifida, are detected prenatally.
Developmental history	Timeliness in attaining milestones in domains of gross motor, fine motor, and social/language development	Did the child meet all milestones on time? In which domains does he or she have delays?	Regression of milestones is a concerning finding that requires further investigation. Patterns in attainment of milestones may also indicate pathology.
Family and social history	Review any pertinent familial health conditions and patterns of development in siblings and parents	Did any of the child’s siblings exhibit similar delays with milestone achievement?	Assessing the family patterns of development may explain or predict findings, particularly in the child with a genetic disorder.
Cognition and social behavior	Screen for age-appropriate cognition and social engagement, including interaction with family and peers	How does the child interact with his or her siblings and peers? Can he or she sustain attention to activities? Does the school have concerns?	Such screening helps identify if deficits are isolated to motor impairments or if cognition is also affected.
Vision and hearing	History of hearing and vision screens, particularly in children with brain injury or brain tumors	Does the child respond when his or her name is called? Does he or she startle to loud noises? Does he or she track objects appropriately?	Testing to ensure adequate functioning of these systems may be indicated. Interventions such as hearing aids, corrective lenses, or visual therapy/exercises can significantly improve a child’s overall level of function when impairments are present. Referral to an audiologist, neuro-optometrist, or vision therapist should be considered if concerns are found.
Speech and language	Screen for impaired production of speech sounds (dysarthria), including intelligibility and quality of speech	Does the child follow basic commands? Can the child make his or her needs and wants known?	Dysarthria can be related to injury of the brain. For example, harsh vocal quality may suggest spastic dysarthria in the setting of an acquired brain injury. Nasal, low-volume speech is typical of flaccid dysarthria associated with conditions such as posterior fossa tumor. Children with dysarthria should be evaluated by a speech therapist. Augmentative and alternative communication may be helpful to improve expressive language in children with significant impairments. Children with dysphonia may benefit from a referral to an otolaryngologist as vocal-fold injections can improve voice quality and volume.

(continued)

Table 32.2. (continued)

Element of history	Key information	Example questions	Implications
Feeding/oromotor function	Review diet and feeding habits, screen for any difficulty with swallow and/or managing secretions, assess for any unexpected weight loss/gain	Does the child eat a variable diet? Does the family notice coughing or change in voice when the child eats/drinks? Is there a history of aspiration pneumonia? Does the child tend to drool?	If the child is experiencing difficulty with feeding/swallowing, then evaluation and treatment with a speech therapist is warranted. If the child is unable to eat by mouth safely, alternative routes of nutrition may be recommended, such as through a gastrostomy tube, to prevent aspiration. If the child has difficulty managing secretions, medications, including glycopyrrolate and botulinum toxin injections to the salivary glands, can be considered.
Mobility and other gross motor skills	Level of assistance the child needs to make transitions from lying down to sitting, to standing, and to taking steps; review use of any orthoses, assistive device, or wheeled mobility use	If the child is ambulatory, how does he or she navigate stairs? Does the child trip or fall often? Does he or she wear leg braces? Does he or she use a wheeled mobility device such as a stroller or wheelchair? Does the child require extra head or trunk support?	Such assessment provides important diagnostic information (i.e., frequent tripping and falling can be caused by a gait impairment that requires further diagnostic workup). A thorough assessment of mobility and gross motor skills will help guide treatment to maximize independence with mobility.
Fine motor coordination	Review for age-appropriate fine motor skills, including dexterity with hand use, grip, and skill	Does the child have a hand preference? Does the child hold the hands fisted? Can he or she transfer toys between hands? Can the child use scissors?	Hand preference usually develops between 2–4 years of age; prior to that time, the child should demonstrate functional use of both hands including reaching for objects. Early hand preference (before 18 months) can indicate weakness of the contralateral hand. A “cortical thumb,” in which the thumb is tightly adducted into the palm, or hands that are tightly fisted are typical findings in a child with cerebral palsy.
Basic and instrumental activities of daily living (ADLs and IADLs)	Screen for the age-appropriate completion of ADLs and IADLs, including feeding, toileting, and using a computer and phone	Can the child self-feed? Does she use utensils appropriately? How much help does he require for dressing?	Most children can accomplish basic ADLs independently by 6 years of age, or first grade in school. Identifying impairments with completing ADL and IADLs will guide treatment.
Participation in recreation and school	Review child's participation in school and play, including school accessibility, home setup, community spaces, and family/caregiver supports and structures	What extracurricular activities does the child enjoy? Where does the child spend most of his or her time?	This can screen for barriers to participation and offer a variety of adaptive sports programs for children with disabilities that provide great opportunities for exercise and socialization.

Prenatal and Perinatal History

The team should consider if the child was born prematurely. This is known to affect neurodevelopment, and prematurity is a major risk factor for **cerebral palsy**. Was there prenatal testing? Many congenital conditions, including **spina bifida**, are detected prenatally by ultrasound (see Chapter 3).

Developmental History

Asking the family about timeliness in attaining milestones in the domains of gross motor, fine motor, and social/language development is essential. Regression

in milestones is a significant finding that requires further investigation. Early attainment of certain milestones may also indicate pathology. For example, early demonstration of a hand preference before the age of 18 months can indicate weakness of the other side. Similarly, early standing due to whole body stiffness can indicate spasticity, as can be seen in cerebral palsy.

Family and Social History

Assessing the health conditions and patterns of development in siblings and parents may help explain or predict findings, particularly in the child with a genetic disorder.

Functional History

The rehab specialist should ask about the child's current level of function in several domains, including the following:

- *Cognition and social behavior:* How does the child interact with his or her family and peers? Can he/she sustain attention to activities? Is the child able to understand age appropriate concepts? Does the school have concerns?
 - *Vision and hearing:* Even when the family does not indicate concerns, testing to ensure adequate functioning of these systems may be indicated, particularly in children with brain injury or brain tumors. Interventions such as hearing aids, corrective lenses, or visual therapy/exercises can significantly improve the child's overall level of function when impairments are present. Referral to an audiologist, neuro-optometrist, or vision therapist should be considered if concerns are found (see Chapters 25 and 26).
 - *Speech and language:* Does the child understand what is said to him/her? Can the child make needs and wants known? Poor intelligibility due to impaired production of speech sounds, known as dysarthria, can be due to a variety of neurological conditions. For example, an acquired brain injury may result in a spastic or hyperkinetic dysarthria, with a harsh, strangled vocal quality. Breathless, hypernasal, low-volume speech is typical of flaccid dysarthria and is seen in a variety of conditions involving the medulla and associated cranial nerves, including posterior fossa brain tumors. All children with dysarthria should be evaluated by a speech therapist. If intelligibility is so poor that reliable verbal communication is not possible, a speech therapist with experience in augmentative and alternative communication (AAC) may be helpful in developing strategies to improve nonverbal means of expression. Children with dysphonia may benefit from a referral to an otolaryngologist with expertise in dysphonia, as vocal-fold injections can improve voice quality and volume (see Chapter 17).
 - *Feeding/oromotor function:* Can the child eat and drink a variety of textures safely? Does the family notice a change in vocal quality, such as a wet voice or coughing when the child drinks? Is there a history of aspiration pneumonia? Does the child tend to drool? If the child has difficulty managing secretions, medications including glycopyrrolate and botulinum toxin injections to the salivary glands can be considered by a psychiatrist or other physician.
- An evaluation and treatment with a speech therapist is also warranted. If the child is unable to eat by mouth safely, the clinician should consider whether a gastrostomy tube placed directly in the stomach is indicated to ensure adequate nutritional intake and whether the child should be prohibited from taking food and fluids by mouth to prevent aspiration (see Chapter 29).
- *Mobility and other gross motor skills:* What level of assistance does the child need to move within the bed, to transition from laying down to sitting to standing, and to take steps? Is the child able to hold his or her head and trunk in an upright, neutral alignment when sitting, or does the child need external support? If the child has a limited ability to ambulate, does he use a wheeled mobility device, such as a stroller or wheelchair? If ambulatory, how does the child navigate stairs? Does he wear any leg braces?
 - *Fine motor coordination:* Hand preference usually develops between 2 and 4 years of age; prior to that time, the child should demonstrate functional use of both hands including reaching for objects. A "cortical thumb," in which the thumb is tightly adducted into the palm, or hands that are tightly fistled are typical findings in a child with cerebral palsy (see Chapter 21).
 - *Basic and instrumental activities of daily living (ADLs and IADLs):* Basic ADLs are the tasks performed every day to take care of oneself in the home environment, such as feeding, dressing, bathing, personal hygiene and grooming, toileting, and transferring. IADLs are higher level skills needed to live in a community; they include managing money, preparing meals, shopping, taking prescribed medication, using a computer and telephone, and housekeeping skills. Most typically developing children can accomplish basic ADLs independently by 6 years of age or first grade in school.
 - *Participation in recreation and school:* It is important to note relevant environmental factors that impact the child's participation in school and play, including school accessibility, home setup, community spaces, and family/caregiver supports and structures. For example, who does the child live with? What community activities do the child and family like to do? What does her day look like? Where does she spend most of her time? What classes or teams does she participate in as an extracurricular activity from school or day care? If none, are there any activities that the child hopes to be involved in the future? There are a variety of adaptive sports

programs for children with disabilities that provide great opportunities for exercise and socialization, such as the Paralympics and Special Olympics.

Physical Exam

The physical exam of the child starts with general observation (see Table 32.3). For example, does the child appear at, above, or below the expected height and weight for age? What is the size and shape of the head, as this often correlates with brain development? Does the abdomen seem distended (constipation is often a challenge in children with limited mobility)?

The focus of the exam is on the neurological and musculoskeletal systems. The neurological exam should include assessment of the child's mental status, cranial nerves, sensation to different modalities, reflexes, coordination (including testing for **dysmetria** [lack of coordination of movements leading to undershooting or overshooting] and **ataxia**) and the presence of any abnormally patterned or adventitious (unusual) movements.

The musculoskeletal exam should include assessment of the active and passive range of motion around major joints of the limbs and neck, the presence of any

abnormal spinal curvature, strength, and muscle tone. Abnormal tone, whether hypertonia or hypotonia, often interferes with development and function. Children with abnormal tone should be referred to a physical medicine and rehabilitation (PM&R) physician for management, including medication and **orthoses** (supports, braces, or splints used to support, align, prevent, or correct the function of limb or joint).

The clinician also needs to test the functional skills that were described during the medical history, considering the following questions:

- How does the child move in the exam room? How does the child transition between surfaces in the room? For example, can he rise from the floor independently?
- Regarding ADLs, can the child take his socks and shoes off and on independently? If given a pen and paper, can he scribble or write in an age-appropriate fashion? Can the child pick up snacks and bring them to his mouth? Does the child demonstrate signs of dysphagia when eating or drinking?
- How does the child interact with his caregiver and others present in the room?

Table 32.3. Physical examination

Elements of physical exam	Key exam features	Implications
General assessment	Weight and height at, above, or below the expected height and weight for age, size and shape of the head, and abdominal distension	Weight and height provide information on development, feeding, and activity level. Head shape correlates with brain development. Abdominal distention may indicate constipation, a common challenge in children with limited mobility.
Neurological assessment	Mental status, cranial nerves, sensation to different modalities, reflexes, coordination (including testing for dysmetria [lack of coordination of movements leading to undershooting or overshooting] and ataxia), and the presence of any abnormally patterned or adventitious (unusual) movements	Quality of movement patterns can provide diagnostic clues. For movement disorders limiting function referral to neurology or a movement disorder specialist may be helpful for pharmaceutical management.
Musculoskeletal assessment	Assessment of the active and passive range of motion around major joints of the limbs and neck, the presence of any abnormal spinal curvature, strength, and muscle tone	Abnormal tone, whether hypertonia or hypotonia, often interferes with development and function. Children with abnormal tone should be referred to a physical medicine and rehabilitation physician for management, including medication therapy and orthoses (supports, braces, or splints used to support, align, prevent, or correct the function of limb or joint). For significant contractures, a referral to orthopedic surgery may be warranted.
Functional assessment	Activity in the exam room, including mobility, such as making transitions from the floor to the exam table to sitting; gross motor skills in older, ambulatory children with age-appropriate tasks such as jumping, hopping, and running; activities of daily living, such as age-appropriate scribbling or writing, how the child transfers toys in his or her hands, whether the child can pick up snacks and bring them to his or her mouth, and whether the child helps with removing shoes/socks; and language and communication, including observing interactions between the child and his or her caregiver, such as if the child communicates needs effectively and the vocal quality of speech	Observation of functional tasks performed in the exam room will provide pertinent information for diagnostics purposes, identifying barriers to progress and formulating a treatment plan.

- Does the child have a typical repertoire of play skills for age?
- Does he demonstrate joint attention?
- Can the child communicate needs? What is the vocal quality of speech?

PRINCIPLES OF TREATMENT

Rehabilitative/functional treatment is a unique multimodal treatment approach that uses interdisciplinary teams to address functional impairments from diverse specialty pathways. The focus of functional treatment, as the name implies, is to optimize the child's functional abilities with the overarching goal to increase the child's access to society and their environment. The objective is to identify the child's strengths and maximize those strengths while concurrently recognizing the physical and social barriers limiting progress. Appropriate treatments and services are offered to specifically target the identified impediments. In the case when a barrier cannot be corrected, the goal becomes focused on measures for accommodation. Treatment ranges from therapeutic management on the individual level to recommendations for improving home accessibility and guidance for navigating environmental restrictions. The interdisciplinary approach allows for comprehensive management that extends into the various sectors of the child's life, including home, school, recreation, and family.

The sections that follow outline the physical and functional treatment approaches for children with three commonly encountered diagnoses that cause developmental disability: cerebral palsy, muscular dystrophy, and spina bifida.

■ ■ ■ CASE STUDY

Thomas is a 5-year-old boy who is followed for spasticity in his lower limbs. He was born prematurely at 28 weeks' gestation. Thomas demonstrated delays in meeting his motor milestones from infancy, although he remained on track with his cognition, language, and communication skills. Given his motor delays, he was referred for early intervention therapy services by his pediatrician at 12 months. When he did begin to walk at 24 months, his parents noted that he consistently walked on his toes, which prompted a referral to the PM&R clinic. On examination, he exhibited bilateral **patellar** (kneecap) hyperreflexia and **clonus** (a series of alternating contractions and partial relaxations of the muscle) in both Achilles tendons, with significant reduction in passive range of motion at the ankles. When walking, he demonstrated toe walking and

exaggerated hip **adduction** (movement toward the midline of the body; see Figure 21.12). The rehabilitation team recommended that Thomas undergo botulinum toxin injections to address hypertonia in the legs, to be followed by serial casting at the ankles and a physical therapy course for stretching, strengthening, and improving range of motion and gait biomechanics. After serial casting, he would be fitted for custom ankle-foot-orthotics.

Thomas has cerebral palsy (see Chapter 21), the leading cause of motor impairment and disability in children, especially those born prematurely (see Chapter 5). Specifically, Thomas has spastic diplegic cerebral palsy. For his functional mobility, he is able to walk independently but would likely have some difficulty with uneven surfaces and with keeping up with his peers. His Gross Motor Function Classification System score would be II (see Table 32.4).

Thought Question:

Apply the ICF model to identify Thomas' health condition, impairments, potential activity restrictions, and participation restrictions.

Cerebral Palsy

Therapeutic Approaches The goals of treatment are unique to each patient. Appropriate interventions for cerebral palsy are based on the child's age, functional abilities, pattern of motor deficits, and associated pain/discomfort. Intervention aims to reduce secondary musculoskeletal deformity rather than to treat the primary central neurological deficit, which is currently not possible. Treatment of children with cerebral palsy is best accomplished by a multidisciplinary team (see Box 32.1). Evaluation and ongoing management by physiatrists and therapists are the mainstays in the care of these children.

Rehabilitative Therapy Physical therapy for children with cerebral palsy addresses functional mobility, gross motor skills, postural control, and muscle strengthening/stretching with activities such as partial-body-weight-support gait training. Occupational therapy focuses on ADLs, fine motor skills, stretching, and range of motion. Speech therapy may be beneficial for children when assistance is needed with feeding, communication, and/or cognition. The ideal frequency and duration of therapy are impacted by critical periods of development, times of significant medical changes, and by interventions such as surgical procedures.

Table 32.4. Summary of the Gross Motor Function Classification System

Level	Age			
	< 2 years	2–4 years	4–6 years	6–12 years
I: Walks without restrictions	Sits well (hands free to play), crawls and pulls-to-stand; walks between 18 and 24 months without a device	Gets up and down from floor to standing without help; walking is preferred method of mobility	Walks indoors and outdoors; climbs stairs; starting to run/jump	Independent walking, running, and jumping, but speed, balance, and coordination are reduced
II: Walks without device; restricted community mobility	Sits but may need hands for balance; may creep or crawl; may pull-to-stand or cruise	Floor sits, but hard to keep both hands free; mobility by crawling, cruising, or walking with assistive device	Transfers with arm assist; walks without device at home and short distances outside; climbs stairs with railing; no running or jumping	Independent walking but limitations in challenging circumstances; minimal running and jumping
III: Walks with assistive device; limited community mobility	Sits with low back support; rolls and creeps	Floor sits, often W-sitting, needs help getting to sit; creeping and crawling primary means of mobility; limited assisted standing/walking	Sits in regular chair with pelvic support to allow free hands; walks with device on level surface; transported for long distances	Walks indoors or outdoors with assistive device; wheelchair mobility or transport for long distances
IV: Limited self-mobility; power mobility	Has head control, but needs trunk support for sitting; rolls to back; may roll to front	Needs hands to maintain sitting; adaptive equipment for sitting/standing; floor mobility only (rolling, creeping, or crawling without reciprocal leg movements)	Adaptive seating needed for maximum hand function; needs assistance for transfers; walks short distances with assistance; power mobility for long distances	Maintains function achieved by ages 4–6 or relies more on power wheelchair for self-mobility
V: Self-mobility severely limited even with assistive devices	Limited voluntary control of movement; head and trunk control minimal; needs help to roll	Limited control of movement and posture; all areas of motor function are limited; adaptive equipment does not fully compensate for functional limitations in sitting and standing; no independent mobility (requires transport); some children achieve very limited power mobility with extensive adaptations		

Adapted from Palisano, R., Rosenbaum, P., Walter, S., Russell, D., Wood, E., & Galuppi, B. (1997). Development and reliability of a system to classify gross motor function in children with cerebral palsy. *Developmental Medicine and Child Neurology*, 39(4), 214–223.

A recent exciting development in the treatment of cerebral palsy has been the use of high-intensity, short-duration constraint-induced movement therapy (CIMT) by physical and occupational therapists in patients with hemiparesis. Here the unaffected limb is restrained with a sling or splint, and intensive

therapy is provided to encourage use of the affected arm. CIMT is based on the concept of “neuroplasticity” and the possibility of developing new neuronal synapses and circuits by promoting use of the affected limb (see Box 32.2; DeLuca, Trucks, Wallace, & Ramey, 2017).

BOX 32.1 INTERDISCIPLINARY CARE

Treatment of Cerebral Palsy

When treating children with cerebral palsy, an adaptive approach is necessary. The involvement of physical, occupational, and speech and language therapy, in combination with medical management, is beneficial to facilitate progress in all developmental domains and to reduce the effect of neurological impairments and comorbidities. The team caring for a child with cerebral palsy may include a pediatrician, developmental pediatrician, physiatrist, orthopedic surgeon, neurologist, neurosurgeon, physical therapist, occupational therapist, speech-language pathologist, therapeutic recreation specialist, orthotist, psychologist, social worker, and dietician. Physiatrists will address tone management, pain management, prescription of orthotic devices and durable medical equipment, and evaluation of seating systems.

BOX 32.2 EVIDENCE-BASED PRACTICE**Constraint-Induced Movement Therapy**

Constraint-induced movement therapy (CIMT) is a technique to improve upper extremity function utilizing high-intensity therapy while constraining use of the less impaired upper extremity. CIMT is a highly efficacious treatment for children with cerebral palsy based on rigorous clinical trials. CIMT can be successfully implemented in the clinical setting. While CIMT has been designated as the most highly recommended form of intervention for children with hemiparetic cerebral palsy, studies have shown that children across a wide range of etiologies and severity levels have shown positive outcomes (DeLuca et al., 2017).

Promoting General Physical Activity Beyond individualized formal therapy, general physical activity and participation in leisure and recreational activities are important and should be encouraged. Adapted physical education in school, as part of an individualized educational program (see Chapter 33), is helpful in establishing a routine for regular participation. In the United States, adapted physical education is a federally mandated part of special education services under the Individuals with Disabilities Education Improvement Act (IDEA) of 2004 (PL 108-446). In the community, adapted playgrounds can offer additional opportunities for physical activity for children with cerebral palsy. Locating these accessible playgrounds, however, can be challenging (see the Additional Resources section at the end of this chapter). Adapted camps offer additional opportunities for participation in leisure and recreational activities. Competitive sports should also be considered and encouraged when appropriate. For the higher level athletes or those aspiring to reach that level, the Paralympics and related preparatory programs can be explored. The International Paralympic Committee is the governing body for the Paralympic movement and can be a resource, but many countries have their own Paralympic committees. For children with cerebral palsy with cognitive impairment, the Special Olympics can be explored. It is important to note that sociodemographic factors (i.e., household income, parent/caregiver education level, and number of parents) have been found to affect level of participation and are part of the health disparities issues addressed in Chapter 42 (Law et al., 2006).

Orthoses and Rehabilitative Equipment Orthoses or splints are frequently used with a goal of maintaining or increasing range of motion, protecting a joint, stabilizing a joint, or improving functional activity. The most common joints splinted are the ankle and the wrist-hand, but orthoses also are made for the trunk

(e.g., dynamic movement orthosis). In addition to orthoses, serial casting, which is the successive application of casts, can be used to increase range of motion. Adaptive equipment can be used to improve functional mobility and/or ADLS. Different examples include wheelchairs, adapted strollers, adapted car seats, positioning chairs, walkers, gait trainers, AAC devices, computer or computer aids, and devices used for environmental control (McMahon et al., 2010). These are further discussed in Chapter 36.

Medication Medication is commonly used in conjunction with therapy, orthoses, and durable medical equipment. Medications for hypertonia are most frequently utilized for spasticity and include baclofen, dantrolene, tizanidine, and benzodiazepines. Of these, baclofen, a gamma-aminobutyric acid B agonist, is used most commonly. Baclofen inhibits overactive neurological signals communicating with the spinal cord. Baclofen and benzodiazepines are used to treat dystonia as well as trihexyphenidyl and carbidopa-levodopa. In addition to oral medication, focal medications in the form of injections are also utilized. Botulinum toxin injections are the most common type of focal treatment. It is injected intramuscularly and acts by inhibiting neurotransmitter release at the neuromuscular junction, which decreases unwanted muscle contraction (see Box 32.3; Copeland et al., 2014; Delgado et al., 2016). Another injectable medication is phenol. Phenol is injected in or near nerves and acts to disrupt signal transmission and conduction to the muscle decreasing unwanted muscle contraction.

Surgery Surgical procedures, primarily neurosurgical or orthopedic, may be recommended. Implantation of an intrathecal baclofen pump is the most common neurosurgical procedure. Rather than administering baclofen by mouth or via an enteral tube, a pump and tubing can be surgically implanted

BOX 32.3 EVIDENCE-BASED PRACTICE**Botulinum Toxin**

Botulinum toxin is used frequently to manage hypertonia (spasticity or dystonia) in the pediatric population. The neurotoxin is injected intramuscularly to create a reversible neuromuscular blockade, causing muscle weakness and a reduction in tone. Goals of botulinum toxin injection include improving motor function and decreasing painful muscle spasms. Botulinum injections are effective for improving ease of care and comfort for nonambulatory children with cerebral palsy. Abobotulinumtoxin A (Dysport) is currently the only botulinum toxin A formulation approved by the U.S. Food and Drug Administration for the treatment of lower limb spasticity in pediatric patients ages 2 years and older. Intramuscular abobotulinumtoxin A approval was based on the positive outcomes of a Phase 3 trial that evaluated lower limb spasticity in pediatric patients with cerebral palsy. The results showed that abobotulinumtoxin A was well tolerated and significantly decreased muscle tone (Copeland et al., 2014; Delgado et al., 2016).

to deliver the baclofen directly to the spinal cord (see Box 32.4; Eek et al., 2018; Hasnat & Rice, 2015).

A surgical procedure considered in some children with spastic diplegia is selective dorsal rhizotomy. In this procedure, dorsal spinal nerve rootlets are cut to decrease the overactive spinal reflex and reduce spasticity in the legs. Selection criteria for this procedure are strict because it is irreversible. Deep brain stimulation is an area of interest in children with primarily dystonia or dyskinesia, but evidence for its effectiveness is limited.

Regarding orthopedic intervention, there are various soft-tissue and/or bony procedures commonly performed, including scoliosis surgery, muscle lengthening, contracture release, and tendon transfers. Orthopedic surgery in patients with cerebral palsy is commonly focused on preventing or treating hip subluxation or dislocation (Wynter et al., 2015).

■ ■ ■ CASE STUDY

Jeffrey is a 4-year-old boy seen because of his mother's concerns related to increased falls and clumsiness in comparison with his peers. Developmentally, he

achieved his motor milestones at a slightly slower rate and did not walk independently until 19 months. He has no other significant past medical history. His mother reports that recently he struggles with getting up off the floor and needs extra help climbing the stairs (see Figure 32.2). He has also started to walk on his toes most of the time. Jeffrey has an older cousin on his maternal side with a similar history who now uses a wheelchair, and Jeffrey's mother has a history of early onset cardiomyopathy. His physical examination is significant for calf hypertrophy and proximal muscle weakness. He has a wide-based gait and walks on his toes. He had laboratory testing and was found to have an elevated creatine kinase level in his blood and a mutation of the dystrophin gene, the genetic defect in Duchenne muscular dystrophy (DMD). He is referred to a neurologist for additional follow-up care.

DMD is the most common progressive childhood neuromuscular disorder (Mah et al., 2014). Chapter 9 provides a full description of typical clinical signs and symptoms, diagnostic testing, and common treatment associated with DMD. This section focuses

BOX 32.4 EVIDENCE-BASED PRACTICE**Intrathecal Baclofen**

Intrathecal baclofen can reduce dystonia and spasticity and thus improve skills such as sitting, communication, and fine motor function in patients with cerebral palsy. Studies demonstrate evidence that intrathecal baclofen reduces pain, aids with sleep, and improves ease of care. The original Ashworth scale to evaluate spasticity is the most commonly used outcome measure in studies of intrathecal baclofen (Eek et al., 2018; Hasnat & Rice, 2015).

Figure 32.2. Gower's sign.

on the critical need for a rehabilitation team to support children with DMD and their family throughout their lives.

Duchenne Muscular Dystrophy

Therapeutic Approaches In accordance with the World Health Organization's ICF, treatment is focused on preserving and maximizing the child's

quality of life and abilities regardless of the stage of the disease. An interprofessional team is critical in the management of a child with DMD. Muscular Dystrophy Association- and Parent Project Muscular Dystrophy-certified care centers are directed by physicians, either physiatrists or neurologists. Treatment focuses primarily on compensatory strategies and the preservation of current function (Birnkrant et al., 2018b; Box 32.5).

BOX 32.5 INTERDISCIPLINARY CARE

Treatment of Muscular Dystrophy

Due to the multisystem involvement of Duchenne muscular dystrophy, optimal management requires an interdisciplinary professional team that works with the patient and the family throughout all phases of the disease process. This team typically includes a neurologist, physiatrist, physical therapist, occupational therapist, speech and language pathologist, orthopedic surgeon, pulmonologist, cardiologist, psychologist, gastroenterologist, and dietician (Birnkrant et al., 2018a).

Rehabilitative Therapy Occupational and physical therapists play key roles as members of the interprofessional team in the management of a child with DMD. Periodic physical assessments aim to monitor the functional progression of the disease and assist with development of an individualized care plan based on the stage of the disease. Therapists focus on maximizing the child's current abilities and maintaining flexibility and strength. Maintenance of strength should never include resistive strengthening exercises or eccentric contractions as these can promote muscle breakdown that cannot be repaired by the body. Treatment strategies emphasize functional training, range of motion, submaximal aerobic exercise programs, splinting for contractures, and recommendations for assistive or adaptive devices for mobility and ADLs (e.g., standard or power wheelchairs; Birnkrant et al., 2018b). Patients are encouraged to avoid unnecessary stair climbing or other activities that stress muscles and require excessive strength. Physiatrists also provide expertise in evaluating equipment and bracing to maximize the child's function. Patients will additionally benefit from periodic evaluation by a speech-language pathologist to monitor and treat challenges with feeding, swallowing, and communication.

Respiratory and pulmonary complications are a major cause of morbidity and mortality in DMD. Cardiologists and pulmonologists are critical team members to follow the child throughout the duration of the disease process. Rehabilitation professionals work closely with the child and family to monitor cardiac and respiratory signs and symptoms to ensure timely follow-up with the appropriate specialist.

Promoting General Physical Activity Patient and family education is critical in guiding a home stretching program, pursuing recreational exercise activities, and modifying school activities. Children with DMD should be instructed to avoid high-resistance strength training and eccentric loading to prevent additional damage to the muscle. Conversely, low-resistance aerobic activity, such as swimming, should be encouraged (Birnkrant et al., 2018b). Recommendations for school may include minimizing stair climbing through the use of elevators and schedule modifications. Preservation of ambulation is critical during the first phase of the disease progression, but it can be saved for mobility in the home or the classroom as well as short-distance ambulation in the community. Treatment strategies include resting/stretching ankle-foot orthoses (AFOs), knee-ankle-foot orthoses for standing and household

ambulation (late ambulatory stage), standing frames, and serial casting.

Of note, toe walking is a compensatory strategy for children with DMD due to progressive, proximal muscle weakness. Toe walking should not be discouraged. A balance of recommended interventions should be employed to preserve ambulation without over-correction of the compensatory mechanisms used by the child to walk (Birnkrant et al., 2018b; Glanzman, Flickinger, Dholakia, Bönnemann, & Finkel, 2011).

Recreational activities are also important for the health and well-being of the child with DMD. Even though individuals with DMD should avoid becoming overly fatigued, this should not limit their participation in recreational activities. They should be encouraged to remain active in the activities they enjoy; they can be transported to the "fun" to preserve energy. Recommendations for sports and recreational activities include cycling, swimming, and other water activities. Participation in recreational teams and events should not stop once the child or adult transitions to a wheelchair for primary mobility. Local and national road races often have a division for duo teams in which one team member will push the other who is in a racing wheelchair. Another activity is Power Soccer, an international team sport for individuals of all genders who use power wheelchairs and cannot play another adaptive sport (Federation Internationale de Powerchair Football Association, 2008).

Orthoses and Rehabilitative Equipment Orthoses or splints are frequently used during rest with a goal of maintaining or increasing range of motion; they are almost never used for boys with DMD during ambulation as they interfere with the ability to obtain a functional posture. Nighttime stretching braces provide a prolonged stretch across the ankle joint and help to maintain length when worn for more than 60 consecutive minutes each day. Recommendations are usually to wear the brace through the night while asleep. Special attention should be paid to adaptive equipment for the bathroom. Grab bars and tub transfer benches make bathing safer when boys are still strong enough to toilet and shower independently. All of the boys will eventually need power wheelchairs, but some will benefit from the use of a manual wheelchair at a younger age to assist with energy conservation during long-distance community ambulation. Lift systems are useful to caregivers when patients require assistance with transfers. As boys become weaker, mobile arm supports and environmental control units can help prolong independence.

Medication Glucocorticosteroids (most commonly prednisone) are currently the most effective pharmacological agents to slow the progressive strength and functional loss and to reduce and stabilize cardiac, respiratory, and musculoskeletal impairments (Birnkrant et al., 2018b; McDonald et al., 2018; Ricotti et al., 2013). Initiation of this therapeutic intervention often occurs after the child demonstrates a plateauing in motor skills, usually around the age of 4 years (Ricotti et al., 2013). Other pharmacological interventions currently under investigation are focused on targeting the primary dystrophin deficit or the secondary pathological mechanisms that result from the lack of dystrophin. Several gene replacement therapies are under evaluation in Phase 1 clinical trials.

Bone health is also of concern related to the side effects from glucocorticosteroid use and overall reduced mobility (Birnkrant et al., 2018a; Guiraud & Davies, 2017). Bone health assessments include urine and serum tests, DEXA scans, and spinal and bone age radiographs, with possible interventions that include supplementation of vitamin D, calcium, and bisphosphonates (Birnkrant et al., 2018a; Guiraud & Davies, 2017; Ricotti et al., 2013).

Lisinopril, an afterload reducer for the circulatory system, is initiated in boys at or about the age of 10 regardless of cardiac function. Early use has been shown to prolong the onset of cardiac failure secondary to cardiomyopathy (Birnkrant et al., 2018a).

Surgery Surgical interventions are indicated to address the development of a progressive scoliosis during the nonambulatory phase. Use of a thoraco-lumbar-sacral orthosis does not slow down the progression of a scoliotic curve. Additional surgical procedures to address contractures and joint deformities for individuals in the nonambulatory phase should be used for specific symptomatic issues, such as positioning in a wheelchair or pain-related issues (Birnkrant et al., 2018b; Hsu & Quinlivan, 2013). Surgical intervention for the preservation of ambulation has mixed outcomes and, if performed, must be closely coordinated by the interprofessional team.

■ ■ ■ CASE STUDY

Leslie is a 15-year-old girl with a past medical history of having a lumbar myelomeningocele that was closed by a neurosurgeon on her first day of life. She additionally had a ventriculo-peritoneal shunt placed to treat **hydrocephalus** (excessive fluid accumulating in the ventricles of the brain) at 3 months of age. She has been followed in the spina bifida clinic at a children's hospital throughout her

life. She catheterizes her bladder every 4 hours to address her **neurogenic** bladder (dysfunction caused by nerve damage) and has a nightly bowel program with an enema for neurogenic bowel. As a young child, Leslie walked with AFOs and a posterior rolling walker. However, she now prefers to use her wheelchair throughout the day. She tells the clinic team that when she uses her chair to get around rather than walking she has more energy for the things she enjoys doing at the end of the school day. She was hospitalized 9 months ago with urosepsis (a potentially life-threatening complication of a urinary infection) related to poor compliance with catheterization. During her hospitalization she developed ischial (pelvic bone) pressure wounds (ulcerations) and is now admitted to the hospital for primary closure of the wounds with plastics surgery. Leslie will be discharged from the acute care hospital to an inpatient rehabilitation facility after surgery. She will work on upper extremity strengthening and safe transfers to prevent surgical wound breakdown and optimization of her bowel and bladder regimen to ensure the wound stays dry and heals appropriately.

Spina Bifida

Spina bifida is the most common birth defect affecting the central nervous system that results in permanent disability. Children with spina bifida present with a spectrum of impairments. Of the neural tube defects, myelomeningocele is the most clinically significant form of spina bifida. Here neural tissue from the developing spinal cord is exposed and degenerates *in utero*, resulting in neurological deficits that vary with the level of the lesion (see Figure 32.3). Disruption of the nerves in the lower spine leads to varying levels of lower extremity paralysis, sensory loss, and bowel and bladder dysfunction. There is a wide range in the level of disability based on multiple factors, including the site of incomplete closure along the spinal cord, the amount of exposed spinal cord, and the timing of surgical intervention (Adzick et al., 2011). In addition, children commonly have further confounding neurologic problems and medical comorbidities that affect their functional independence (Box 32.6).

Therapeutic Approaches Currently, there is no treatment technique to repair or replace damaged nerves in the spinal cord. Thus, treatment for children with spina bifida is aligned with the ICF model to focus on maximizing independence, increasing self-advocacy, and optimizing community participation (see Figure 32.4). In addition, children with spina bifida require frequent surveillance for potential neurological, urologic, skin,

Figure 32.3. Normal neural tube development compared with spina bifida with meningocele. A) The typical formation of the neural tube (i.e., the precursor of the spinal column) during the first month of gestation. B) Complete closure of the neural groove has occurred; the vertebral column and spinal cord appear normal in the cross-section on the left and the longitudinal section on the right. C) Incomplete closure of an area of the spine is called spina bifida and may be accompanied by a meningocele, a sac-like abnormality of the spinal cord. Because nerves do not normally form below this malformation, the child is paralyzed below (or caudal to) that point.

BOX 32.6 INTERDISCIPLINARY CARE

Treatment of Spina Bifida

- Children with spina bifida require close medical management by interdisciplinary teams that include neurosurgeons, physiatrists, orthopedic surgeons, urologists, physical therapists, occupational therapists, dietitians, and social workers.
- Children with spina bifida will benefit from periodic physical and/or occupational therapy throughout their lives. Infants and toddlers have access to home and school-based services through early intervention services, which are part of the Individuals with Disabilities Education Improvement Act (IDEA) of 2004 (PL 108-446).
- A variety of surgical providers are involved in the care of children with spina bifida throughout their lives: Neurosurgeons closely follow patients with spina bifida to screen for and treat possible associated disorders; orthopedic surgeons manage the associated contractures and joint deformities that may occur; and urological surgical interventions are aimed to improve bowel and bladder function and continence.
- The goal when treating children with spina bifida is to maintain stable neurological functioning throughout the patient's lifetime. Rehabilitative specialists and therapists help to monitor neurological functioning.

Figure 32.4. Rehabilitation goals.

and musculoskeletal complications that can further limit function and increase morbidity.

When working with children with spina bifida it is important to identify the highest neurologic level of maintained strength and sensation. Once established, this neurological level serves as a functional prognosticator and guides medical decision making, including identification of specific equipment needs and therapy goals. In addition to the preserved level of neurological integrity, independence with mobility and self-care in children with spina bifida is influenced by environmental and physical factors such as contractures, joint deformity, weight, cognitive function, family support, and access to resources.

Rehabilitative Therapy Children with spina bifida benefit from periodic physical and/or occupational therapy throughout their lives. It is not uncommon for patients with spina bifida to reengage with therapy services during critical points in development

or after medical or surgical interventions. Habilitative therapy should be initiated early in the patient's life. Home- and school-based services can be accessed through early intervention services.

Occupational and physical therapy support the child in multiple areas, including gross motor development and the advancement of self-care skills. These self-care skills typically include wheelchair transfers, bladder catheterization, skin inspection for pressure ulcers, general hygiene, dressing skills, and donning and doffing orthoses. Exercise regimens focus on active and passive range of motion, stretching, functional strengthening, supported standing programs for weight-bearing benefits, and positioning to maintain good postural alignment. Through development of a home exercise program, therapists will provide the child and family with the skills to be successful in skin care and bowel and bladder management as well as mobility in the home and community.

Promoting General Physical Activity Ambulation potential and functional ability will vary in each child based on the neurological level of the lesion. Additional medical and social variables include cognitive function, weight, access to resources, and comorbidities. Even if community and household ambulation is not possible, therapeutic ambulation has both physiologic and psychologic benefits. Despite the level of the lesion, mobility independence through the use of orthoses and/or mobility equipment such as wheelchairs and scooters is possible and should be encouraged (Apkon et al., 2014; Copp et al., 2015).

Participation in adapted sports is a way for children with spina bifida to optimize their physical and physiological functioning (Shapiro & Malone, 2016). Involvement in sports is also associated with an increase in social support systems and improvements in feelings of self-worth and quality of life (Shapiro & Martin, 2014). In contrast, there is significant risk for weight gain and development of comorbidities due to inactivity in spina bifida patients. Children with varying levels of neurological involvement can participate in a variety of adapted sports activities including para-sports such as skiing, tennis, and basketball. Patients with spina bifida, like patients with other spinal cord injuries, who demonstrate impairments in muscle power and range of motion, are still among the most represented athletes in the Paralympics (International Paralympic Committee, 2015).

Orthoses and Rehabilitative Equipment

Patients with spina bifida usually need a variety of orthoses and rehabilitative equipment throughout their lives. The type of orthoses and equipment will vary depending

on the neurological level of the lesion, clinical presentation, age of the patient, and patient and family needs. Specialized equipment might be needed to achieve these goals, and rehabilitative specialists and therapists can make appropriate equipment and orthotic recommendations. Treatment of individuals with a higher thoracic (chest)–level lesion may emphasize sitting balance and wheelchair mobility, whereas the therapeutic focus for a child with a lower sacral (back)–level lesion may be higher level balance and gait exercises with a goal of participation in sports. Table 32.5 outlines expected functional mobility and equipment needs based on level of impairment. Due to absent sensation below the neurological level of the meningocele, children are at risk for skin breakdown with any ill-fitting orthotics or devices. Therefore, children and families will benefit from education on the need for vigilant skin checks and utilization of pressure relief techniques.

Medication There are no pharmaceutical options to manage the neurological impairments of spina bifida. Pharmaceutical treatments are focused on improving function of and continence of stool and urine. Medications are frequently recommended to decrease bladder storage pressure, improve urinary continence, prevent urinary tract infection, and promote regular bowel movements to prevent constipation. The need for medications to address issues such as increased pain, frequent nausea and vomiting, or increased tone may signal a complication such as shunt failure or tethered cord that needs further workup.

Surgery Surgical interventions for spina bifida usually begin at or even before birth and will continue

Table 32.5. Functional mobility and equipment needs based on level of impairment in children with spina bifida

Motor function	Level of muscle involvement	Expected potential for ambulation	Recommended orthoses for functional or therapeutic ambulation	Durable medical equipment
T12	Abdominal paraspinal	Nonfunctional ambulation; Therapeutic only	RGO	Stander (at young age) Manual wheelchair (may require power assist)
L1	Hip flexors	Household and therapeutic	Long leg: RGO, HKAFO	Manual wheelchair, stander
L2-3	Hip adductors	Household and therapeutic	Long leg: RGO, HKAFO	Manual wheelchair, forearm crutches
L4	Knee extensors	Household +/- community	Short leg: AFO	Manual wheelchair, forearm crutches
L5-S1	Ankle dorsiflexors, ankle invertors, toe extensors	Community ambulation	Short leg: AFO or SMO	+/- Forearm crutches, cane
S2	Ankle plantar flexors	Community ambulation	Foot orthoses	None

Key: RGO, reciprocal gait orthosis; HKAFO, hip-knee-ankle-foot orthosis; AFO, ankle-foot-orthosis; SMO, supra-malleolar orthosis.

BOX 32.7 EVIDENCE-BASED PRACTICE**Randomized Trial of Prenatal Versus Postnatal Repair of Myelomeningocele**

A randomized control trial compared outcomes of *in utero* repair of myelomeningocele with standard postnatal repair. Eligible women were assigned to undergo either prenatal surgery before 26 weeks' gestation or standard postnatal repair. The trial was stopped for efficacy of prenatal surgery after the recruitment of 183 of the planned 200 patients. Results revealed that prenatal surgery for myelomeningocele reduced the need for shunting and improved motor outcomes at 30 months but was associated with maternal and fetal risks (Adzick et al., 2011).

throughout the patient's life. A number of surgical specialists are involved in the care of children with spina bifida, including neurosurgeons, orthopedic surgeons, and urologists. An infant with spina bifida will undergo his or her first neurosurgical intervention within 24–48 hours of birth to repair the primary spinal cord defect. Repair of the spinal cord defect during fetal life is now available to appropriate candidates, as studies have shown positive outcomes associated with prenatal myelomeningocele repair by intrauterine surgery for eligible patients (Adzick et al., 2011; see Box 32.7).

Neurosurgery involvement does not stop after closure of the spinal cord defect and is a routine feature in the management of the spina bifida population. Neurosurgeons follow patients with spina bifida closely to screen for and treat possible associated disorders, including Arnold Chiari malformation, hydrocephalus, syringomyelia, and tethered cord (Bowman & McLone, 2010). Orthopedic surgeons manage the associated contractures and joint deformities that may occur from muscular imbalances in the hips, legs, feet, or spine. Goals of urological surgical interventions are to improve bowel and bladder function and continence. Examples include bladder augmentation and Malone antegrade continence enema.

SUMMARY

- The assessment of a child with disabilities relies on both the medical history and physical exam, with an emphasis on gross and fine motor skills as well as cognition, language, and social skills.
- The ICF model of function allows the provider to relate the child's health problem to how it affects their body systems, their personhood, and their interactions with society.

- Loss of skills or milestones is not consistent with cerebral palsy and may indicate a neurodegenerative disorder.
- An early reliable marker for ambulation in the child with cerebral palsy is the ability to sit independently by 2 years of age.
- Avoid progressive resistive strength training and eccentric exercises in patients with DMD to prevent further damage to the muscles.
- Management of respiratory and cardiac complications is paramount for preservation of quality of life and increase in the overall lifespan of an individual with DMD.
- Children with spina bifida require comprehensive surveillance to prevent neurological, urologic, and skin complications that can limit function and increase morbidity.
- Due to absent sensation below the neurological level, children with spina bifida are at risk for skin breakdown and require the incorporation of skin checks and pressure relief techniques into their daily routine.

CHAPTER 33

Special Education Services

Elissa Batshaw Clair

Upon completion of this chapter, the reader will

- Be aware of the history of special education services
- Be familiar with the Individuals with Disabilities Education Improvement Act of 2004, Every Student Succeeds Act, and other legislation pertaining to education for students with disabilities
- Be knowledgeable about services and supports available for students with disabilities
- Understand the components of an individualized education program
- Understand the roles of a special education teacher

Special education is defined by the Individuals with Disabilities Education Improvement Act (IDEA) of 2004 (PL 108-446) as “specially designed instruction, at no cost to parents, to meet the unique needs of a child with a disability” (§ 602[29]). Special education includes direct educational instruction by a special education teacher; related services such as language therapy, speech therapy, physical therapy, occupational therapy, or social work services; paraprofessional support; or consultation from a special education professional to the general education teacher. All special education services are individualized to provide the instruction necessary to reach each student’s goals. IDEA 2004 guarantees a free appropriate public education (FAPE) for all students with disabilities ages 3–21. A zero-reject provision mandates that even students who have severe and

multiple impairments have the right to a FAPE in the least restrictive environment (LRE).

Before the enactment of the Education for All Handicapped Children Act of 1975 (PL 94-142), the educational needs of millions of students with disabilities were not being fully met. Students with disabilities did not receive appropriate educational services, were excluded entirely from the public school system and from being educated with their peers, had undiagnosed disabilities that prevented them from having a successful educational experience, or faced a lack of adequate resources within the public school system, requiring them to find services outside of the public school system (PL 108-446 § [601][c][2]).

Since the 1970s, legislation has attempted to address each of these issues. Figure 33.1 summarizes the history of educational law.

Elementary and Secondary Education Act of 1965 (PL 89-10)	Attempted to correct unequal educational opportunities that resulted from a child's economic condition
Education of the Handicapped Act (EHA) of 1970 (PL 91-230)	Amendment to earlier legislation that established a core grant program for local education agencies (LEAs) to provide services for children with disabilities
Pennsylvania Association of Retarded Citizens (PARC) v. Commonwealth of Pennsylvania (1971)	PARC proved • All children with intellectual disability are capable of benefiting from a program of education and training • Education cannot be defined as only the provision of academic experiences for children • Having undertaken to provide all children with a free appropriate public education (FAPE), the state could not deny students with intellectual disability access to FAPE • The earlier students with intellectual disability are provided education, the better the predictable learning outcomes (Yell, 1998).
Education for All Handicapped Children Act of 1975 (PL 94-142)	• Provided FAPE to all school-age children, regardless of their disability • Was a funded program • Defined the disabilities that would be covered and established guidelines for fair evaluation and assessment
Education of the Handicapped Act Amendments of 1986 (PL 99-457)	• Extended special education services to infants and pre-schoolers • Developed an individual family service plan (IFSP) for infants and toddlers in early intervention programs (Mercer, 1997)
Individuals with Disabilities Education Act (IDEA) of 1990 (PL 101-476)	• Used person-first language and replaced the word handicap with disability • Arranged for transition planning to occur to help students progress from high school into adulthood (Mercer, 1997) • Emphasized meeting the needs of ethnically and culturally diverse children with disabilities • Indicated early intervention programs to address the needs of children who were exposed prenatally to maternal substance abuse (Mercer, 1997)
Individuals with Disabilities Education Act Amendments of 1997 (IDEA '97; PL 105-17)	• Strengthened the role of parents • Gave increased attention to racial, ethnic, and linguistic diversity to prevent inappropriate identification and mislabeling • Ensured that schools are safe and conducive to learning • Encouraged parents and educators to work out their differences by using nonadversarial means

Figure 33.1. History of educational law prior to the current law, the Individuals with Disabilities Education Improvement Act (IDEA) of 2004 (PL 108-446).

■ ■ ■ CASE STUDY

Mateo did not walk or speak his first word until 18 months. As a toddler, he received speech therapy in his home once per week in accordance with an **individualized family service plan (IFSP)** provided under Part C (Infants and Toddlers with Disabilities) of IDEA. These services were designed to help Mateo's parents facilitate their son's communication skills. When Mateo entered

kindergarten, he was soon identified as having significant delays compared with his classmates and as needing special education services. His parents gave permission for testing, which showed him to be functioning in the range of mild intellectual disability. He was thus eligible for special education services.

An **individualized educational program (IEP)** was developed for Mateo with input from a team consisting

of a psychologist, a general education teacher, a special education teacher, a speech-language pathologist, and his parents. The IEP identified the goals for Mateo, the amount of time he would receive special education services, and the **related services** that would be provided to support his educational progress.

The IEP team had a formal discussion that included reviewing information from Mateo's most recent evaluations as well as data collected by teachers and parental input. They determined that the most appropriate placement for Mateo was in an inclusive environment in a class containing students both with and without disabilities. The class was cotaught by a general education and special education teacher. (Ideally this class would be cotaught throughout the entire day, but it is more typical for classes to be cotaught for portions of the day, with only the general education teacher teaching the other portions.) The two teachers worked together to ensure that all students, including Mateo, could have access to the same core curriculum with differentiated instruction and **modifications** to the schoolwork. The team also decided that Mateo would require related services from a speech-language pathologist. Sometimes this therapist would teach a lesson to all or part of the class; at other times, she worked with Mateo individually.

Mateo made good progress in this program and was reassessed regularly so that his IEP could be adjusted. When Mateo was 16 years old, he began the transition planning process mandated by IDEA. With his input during a transition-planning inventory, a **transition IEP** was developed. Mateo was very interested in cooking, often preparing creative meals at home. He chose to attend prevocational food service classes in addition to his academic courses. The high school offered career cluster experiences in culinary arts, and Mateo continued taking vocational classes, honing his skills as a chef. With the help of a job coach provided by the Bureau of Vocational Rehabilitation, Mateo secured a summer job at a local restaurant. He continued in his school program through age 21 because special education legislation offers services through this age for students with disabilities who 1) have not earned all of their credits toward graduation, 2) need additional transition services, or 3) are earning an alternative certificate rather than a general education diploma. Beginning in 11th grade, when Mateo was 17, he worked half days at the restaurant while continuing to attend school part time. At 20 years of age, he enrolled in culinary classes at a community college as part of his ITP. At age 21, he completed his public education, received a diploma, and was subsequently hired full time as an assistant chef at the same restaurant.

Thought Questions:

What are the components and sequence of multitiered systems of support (MTSS)? What are the ways that special education teachers can facilitate learning?

PREVALENCE AND EPIDEMIOLOGY

Eligibility for Special Education

Eligibility for special education services is defined by IDEA 2004. Two other laws, Section 504 of the Rehabilitation Act of 1973 (PL 93-112) and the Americans with Disabilities Act (ADA) of 2008 (PL 110-325), also define avenues for students with disabilities to receive special services. Another law affecting special education but not directly pertaining to eligibility, Every Student Succeeds Act of 2015 (PL 114-95), will be addressed later in this chapter.

Individuals with Disabilities Education Improvement Act of 2004

For a student to receive special education services, he or she must have a physical, cognitive, or behavioral impairment that interferes with the ability to benefit from instruction in the general classroom curriculum. Students who qualify as having a disability under IDEA are provided services through an IEP. The specific disabilities recognized by IDEA Part B Regulations (34 C.F.R. § 300.8 [a]) fall under the following categories:

- Intellectual disability
- Hearing impairments (including deafness)
- Speech or language impairments
- Visual impairments (including blindness)
- Emotional disturbances
- Orthopedic impairments
- Autism
- Traumatic brain injury
- Other health impairments (including chronic diseases and attention-deficit/hyperactivity disorder [ADHD] if they impair educational performance)
- Specific learning disabilities
- Deaf-blindness
- Multiple disabilities
- Young child with a developmental delay (ages 3–9)

Autism is the fastest growing of these categories. For the 2009–2010 school year, there were 378,000 students identified with ASD. This accounted for 5.8% of the special education population and 0.8% of the general population. Five years later (2014–2015), there were 576,000 students identified with ASD. This accounted for 8.8% of the special education population and 1.1% of the general population. One area of eligibility that is shrinking is emotional disturbance (ED). Within that same time frame, the number of students qualifying for IEP services as students with ED fell from 420,000 to 349,000, or from 6.5% to 5.3% of the special education population and from 0.9% to 0.7% of total student enrollment (U.S. Department of Education, 2016).

Related Services within Special Education

In addition to the academic services provided by the teacher, students with disabilities are eligible to receive related services. The term **related services** is defined as “transportation and such developmental, corrective, and other supportive services . . . as may be required to assist a student with a disability to benefit from special education” (PL 108-446, § 601[26]). According to IDEA 2004 (PL 108-446, § 602[26]), these services include the following:

- Speech-language pathology and audiology services
- Psychological services
- Physical and occupational therapy
- Recreation, including therapeutic recreation
- Social work services
- Counseling services, including rehabilitation counseling
- Orientation and mobility services, including therapeutic recreation
- Medical services
- Nurse services

Table 33.1 summarizes the types of related services that may be provided for individuals by disability.

Section 504 of the Rehabilitation Act of 1973 and the Americans with Disabilities Act Amendments Act of 2008

The basic concept of IDEA is that of zero reject—in other words, the public school system must accommodate or find alternate accommodations at public expense for every student with a defined disability.

If a student does not satisfy the IDEA 2004 criteria for disabilities, he or she may still receive the benefit of access, accommodations, and special services through Section 504 of the Rehabilitation Act of 1973 (PL 93-112) or the ADA of 2008 (PL 110-325), where the objectives and language are similar. These two acts are intended to establish a “level playing field” by eliminating barriers that exclude people with disabilities from participation in the community and workplace. They attempt to eliminate hurdles and discrimination that prevent or hamper participation, whether physical (e.g., steps instead of ramps) or programmatic (e.g., exclusion of a student with HIV from the classroom). The ADA creates access to physical barriers. An example of this is mandating an elevator or lift in a school building if needed for a student with a physical disability. Section 504 of the Rehabilitation Act of 1973 creates access to programmatic needs. An example of this is requiring a place to rest and shortened assignments if needed for a student with cancer who is receiving chemotherapy.

The definition of disability is broader under Section 504 than under IDEA 2004. Although Section 504 covers the majority of students covered by IDEA 2004, the reverse is not the case. Specifically, Section 504 protects people who have a physical or mental impairment that substantially limits one or more major life activities, have a record of such an impairment, or are regarded as having such an impairment. Examples of major life activities include functions such as caring for oneself, performing manual tasks, walking, seeing, hearing, speaking, breathing, learning, and working (34 C.F.R. 104.3[j][2][ii]). Congress further refined this list to include eating, sleeping, standing, lifting, bending, reading, concentrating, thinking, and communicating (U.S. Department of Education, Department of Civil Rights, 2016). In addition, mitigating measures (such as medication, medical supplies, equipment or supplies, low vision devices, mobility devices, prosthetics, hearing aids and cochlear implants, etc., with the exception of ordinary glasses or contact lenses) cannot be considered when determining disability under 504 determinations. For example, the members of the 504 team would not be permitted to determine that, because a student’s ADHD medication is effective, that student is not disabled under section 504. As another example, the 504 team cannot determine ineligibility for a student with hearing aids or a cochlear implant because the student is able to process sound well enough to communicate (Office of Civil Rights, 2015).

The following are examples of students who may be covered by Section 504 to receive special services but not by IDEA 2004:

Table 33.1. Examples of disabilities and typical related services provided

Services										
Disability	Speech-language pathology	Audiology	Behavior support and counseling	Physical therapy	Occupational therapy	Vision (orientation and mobility)	Social work	Assistive technology	Transportation	Medical services
Vision impairment			X		X	X	X	X	X	
Hearing impairment	X	X	X				X	X	X	
Intellectual disability	X		X	X			X	X	X	
Autism	X		X		X		X	X	X	
Other health impairment: Attention-deficit/hyperactivity disorder			X				X	X	X	
Learning disabilities			X				X	X		
Orthopedic impairment: Cerebral palsy	X		X	X	X		X	X	X	X
Traumatic brain injury	X		X	X	X		X	X	X	X

- Students with communicable diseases (e.g., HIV)
- Students with food allergies
- Students with asthma
- Students with attention disorders without significant academic deficiencies
- Students with Tourette syndrome, epilepsy, diabetes, or cancer
- Students with impairments as a result of emotional illness or former misclassification of intellectual disability (Office of Civil Rights, 1995)

Attention-Deficit/Hyperactivity Disorder: IDEA or 504

Students diagnosed with ADHD may require 1) services under IDEA in the category of Other Health Impairment, 2) services under Section 504 of the Rehabilitation Act, or 3) no services that differ from other general education students at their school. Making the decision of whether a student requires an IEP or a 504 plan is individual and based on a team decision after weighing that student's unique strengths and weaknesses. Examples of educational needs that may require accommodations, modifications, or instruction in students with ADHD include the following:

- Difficulty sustaining attention during instruction or when presented with assignments
- Difficulty following multistep directions (working memory)
- Tendency to misplace assignments/supplies
- Difficulty completing long-term assignments (organization)
- Behavior problems (impulsivity, oppositional defiant behavior)

When deciding between an IDEA identification and a 504 plan, the team should consider whether the student needs accommodations, modifications, or specialized instruction to allow him or her access to the general education curriculum. For students whose needs can be served by accommodations, the team may determine that a 504 plan is the most appropriate action. Accommodations for students with ADHD may include shortened assignments without changing the difficulty level; written, multistep directions; or assistance with writing assignments in a daily planner. For students who need specialized instruction, the team may determine that an IEP will most appropriately address deficits in social skills, self-monitoring, accessing memory, regulating alertness, or sustaining effort. For students who require modifications such as

lowering the difficulty level of assignments or shortening assignments so that integral portions are omitted, the team may develop an IEP after carefully weighing both options and considering additional factors.

Other Factors That Define Disability

Nondiscriminatory Assessment and Eligibility

Public schools are obligated to provide a nondiscriminatory evaluation for any student suspected of having a disability. This includes students enrolled in private schools and students ages 3–5 years who are not yet registered for school. Implementing this requirement varies from state to state. In addition to having access to official preschool Child Find programs (see Chapter 31), generally parents can bring their child to the local school district and request an evaluation. The stated purpose of the initial evaluation is to determine whether a child has a disability and, if present, to establish the student's educational needs (PL 108–446, §§ 612 [a][10][A][ii] and § 614[a] [1][A]).

Parents must consent prior to an evaluation. This consent, however, is not consent for placing the student in a special education program, which must be obtained separately. A student is usually evaluated by a multidisciplinary team consisting of a psychologist and one or more of the following education professionals: speech-language pathologist, occupational therapist, physical therapist, and social worker. The evaluation team should use a comprehensive assessment process to address the student's strengths, interests, goals, and needs in order to determine whether and which special education services are required. The evaluation may include tests of intelligence, academic skills, memory, visual-motor integration, adaptive behavior, reading, math, written expression, social-emotional skills, motor skills, sensory integration, speech, and language. For students whose cognitive functioning is at a preschool level, testing focuses on communication, social, motor, and adaptive skills.

The multidisciplinary team must follow specific guidelines during the student's evaluation. These guidelines were created in response to certain faulty evaluation practices in the past, which led to many students (especially minority students; see Chapter 42) being incorrectly diagnosed and placed in special education. Many minority students who functioned appropriately outside of school were classified as "intellectually disabled" based on a single IQ test. This injustice was first formally recognized with the *Larry P. v. Riles* federal court case in California in 1972. A group of African American students complained that they had been inappropriately placed into special education classes for students with "educatable

mental retardation" (EMR) based on intelligence tests that were biased against children of color. The justices ruled that these very common intelligence tests (WISC and Stanford-Binet) were indeed biased and resulted in a disproportionality large percentage of African American students in EMR classes. The court ruled that standardized intelligence tests were no longer to be used in the state of California to determine placement in EMR classes (Bersoff, 1980). With this type of inequity in mind, a number of mandates for nondiscriminatory evaluation procedures were installed as part of IDEA 1990 and continue in IDEA 2004 today. The key mandates are that 1) several tests must be used to determine whether the student has a disability and 2) parental input must be included (PL 108-466, § 614[a][2][A–C] and 614[b][3][A]).

With increasing concerns about the rising number of students classified as having a learning disability, IDEA 2004 prohibits eligibility decisions from being made based on a lack of instruction or as a result of limited English proficiency (PL 108-446, § 614 [b][5][A–C]). Reevaluation of a student with a disability is required to take place no more than once per year or less than once every 3 years unless the parent and local education agency agree that the timelines should be altered.

General Education Legislation Affecting Special Education

The Every Student Succeeds Act (ESSA) of 2015, which is a reauthorization of the Elementary and Secondary Education Act of 1965 (PL 94-142), refines IDEA in four areas: 1) alignment of IEP goals to state academic content standards, 2) inclusion in state high-stakes assessment for all students (including the use of alternative assessments based on alternative academic achievement standards, 3) the use of universal design for learning in assessments, and 4) the disaggregation of students with disabilities into a subgroup for accountability purposes. The purpose of these regulations is to ensure that all students with disabilities are educated to the same high standards as their peers without disabilities (Council of Chief State School Officers, 2016).

Endrew F. v. Douglas County In 2017, the Supreme Court changed the provisions of special education with their ruling in the case of *Endrew F. v. Douglas County*. Endrew was a student with autism spectrum disorder whose parents believed that he was not being afforded the opportunity to make progress in his public school. They had unilaterally placed him in a private school (where he was making progress) and were seeking reimbursement for his tuition fees. Prior to this case, school districts were required to provide services that met the "merely more than *de minimis*"

standard, meaning that the student must be provided enough services to achieve "some" benefit from their education. This was a result of the 1982 *Board of Education v. Rowley* Supreme Court case. In the case of *Board of Education v. Rowley*, Amy was a student with a hearing impairment. The school system had provided her with a tutor, speech therapist, and an FM unit for the teacher to amplify the teacher's words. Amy's parents wanted the school to provide a sign language interpreter. However, Amy was making adequate progress with the supports provided. The court determined that students with IEPs need only be provided with the services necessary to benefit from their education (*Endrew F. v. Douglas County*, 2017). This 2017 ruling found that the "merely more than *de minimis*" standard did not provide FAPE. Educational institutions are now required to provide "an educational program [that] must be appropriately ambitious in light of [the students] circumstances" (p. 14). For a student to be fully included in the general education classroom, an IEP typically should be "reasonably calculated to enable the student to achieve passing marks and advance from grade to grade" (p. 1). For students who are not included in the general education classroom, the ruling was less clear. However, Justice Roberts wrote that "A student's IEP need not aim for grade-level advancement if that is not a reasonable prospect. But that student's educational program must be appropriately ambitious in light of his circumstances" (*Endrew F. v. Douglas County*, 2017, p. 3).

Racial Disparity One of the goals of IDEA 2004 was to reduce the overrepresentation of minorities in special education. While the reduction of minorities in special education (especially in the area of intellectual disability) remains a goal of the federal government, newer analysis has indicated that discrimination of minorities is through both overrepresentation and underrepresentation in special education (see Chapter 42).

GOALS OF TREATMENT: THE INDIVIDUALIZED EDUCATION PROGRAM

An IEP indicates the special educational services a student will receive and the expected achievement with the support of these services over the course of the school year. According to IDEA 2004, these goals must be developed based on 1) the strengths of the student; 2) the concerns of the parents; 3) the results of the most recent evaluation of the student; and 4) the academic, developmental, and functional needs of the student (§ 614[d][3][A]). IEP goals must also align with state grade-level academic content standards. A new

IEP must be written at least once per year and should be modified as often as needed based on an assessment of the student's progress. In addition, an IEP can be amended when changes are necessary (as opposed to rewriting the entire IEP) if the changes are covered within the time frame of the original IEP.

Format and Content

The law is very specific about what must be included in an IEP. According to IDEA 2004, with additions as required by ESSA of 2015 (Council of Chief State School Officers, 2016), an IEP must contain the following items (PL 108-446, § 614 [d][1][A]):

- A statement of the student's present level of academic achievement and functional performance and how the student's disability affects participation in the general curriculum
- A statement of measurable annual goals, including academic and functional goals, which are aligned to state grade-level academic content standards (or alternate academic standards for students with the most significant cognitive disabilities)
- A description of how the student's progress toward the annual goals will be measured
- A statement of the special education, related services, and supplementary aids and services, based on peer-reviewed research to the extent practicable, that will be provided to the student or on behalf of the student
- A statement of modifications or supports for school personnel that will be provided for the student
- An explanation of the extent, if any, to which the student will not participate with students who do not have disabilities in the general education classroom
- A statement of any individual modifications that are needed for the student to participate in statewide or districtwide assessments of student achievement, including information as to if a student will be participating in alternate assessment (based on Alternate Academic Achievement Standards for students with the most significant cognitive disabilities, not to make up more than 1% of the student body)
- A statement of the projected date for the beginning of the services and modifications, along with descriptions and an indication of the anticipated frequency, location, and duration of those services and modifications
- A statement for students 16 years or older of post-secondary goals based on age-appropriate transition assessments related to training; education; employment; and, when appropriate, independent living skills

Personnel

Members of an IEP team include the parent(s); the student (when appropriate); the special education teacher; representatives of related services (such as therapists and social workers); the general education teacher (if the student is likely to participate in the general education environment); the psychologist (see Box 33.1); an interpreter if needed; a representative of the local educational agency, which is normally the school district; and an individual who can interpret evaluation results (PL 108-446, § 614 [d] [1][B] [i-vii]).

Establishment of the Least Restrictive Environment

IDEA 2004 emphasizes that the general education classroom is the appropriate beginning point for planning an IEP. A more restrictive placement should be considered only when participation in the general education classroom is demonstrably not beneficial to the student. Even students with severe cognitive impairments have benefited academically and socially from being educated in an inclusive environment (Williamson, McLeskey, Hoppey, & Rentz, 2006). IDEA clearly states that the need for modifications to the general education curriculum is by itself not a valid reason for placing a student in a more restrictive educational setting. According to the U.S. Department of Education's Office of Special Education and Rehabilitative Services, the appropriate placement of a student should be made based on the

educational benefits available to the disabled student in a traditional classroom, supplemented with appropriate aids and services, in comparison to the educational benefits to the disabled student from a special education classroom; the non-academic benefits to the disabled student from interacting with nondisabled students; and the degree of disruption of the education of other students, resulting in the inability to meet the unique needs of the disabled student. (1994, p. 7)

Although IDEA 2004 promotes inclusion, FAPE is the primary requirement for the education of students with a disability. For students with severe disabilities, the full continuum of placements, including education

BOX 33.1 INTERDISCIPLINARY CARE**The Role of the School Psychologist**

The school psychologist is the gatekeeper to special education, but they have many functions in that role. The school psychologist has the greatest role in the Child Find requirement of the Individuals with Disabilities Education Improvement Act (IDEA) of 2004 (PL 108–446). They are generally the team member that coordinates the evaluation, and they conduct most of the assessments, such as administering tests of intelligence, academics, or emotional functioning. The school psychologist also conducts interviews with parents, teachers, and students, as well as conducts observations of the student in the school environment. In addition, the school psychologist also plays an important preventive role. They work with individual students, families, teachers, and administrators to enable students to be successful in general education and to prevent a placement in special education that could have been avoided. The school psychologist provides counseling to individual students and develops and monitors individual academic and behavioral improvement plans. They connect families to community resources and improve school-family partnerships. The school psychologist works with teachers to facilitate small-group academic and behavioral supports within their classrooms. They work with administrators to facilitate schoolwide multi-tiered systems of support–response to intervention programs for both schoolwide systems of academic growth and positive behavior interventions and support for schoolwide behavioral management.

in separate classrooms or separate schools, may be the most appropriate (Kauffman & Badar, 2016).

There has been a significant decrease in the time students spend in separate settings for special education in the past 2 decades. Between 1989 and 2013, the percentage of students with disabilities receiving services outside of the general education environment for 80% or more of the day was halved, from 69% to 38% (U.S. Department of Education, Office of Special Education and Rehabilitative Services, 2015). Table 33.2 summarizes the different approaches and environments for providing special education services and the distribution of students within these environments.

Development of Annual Goals and Benchmarks or Objectives

IDEA 2004 requires the development of measurable annual goals to enable parents and educators to determine a student's progress. These goals should address both academic and nonacademic concerns and be based on the student's current education and behavior level and aligned to state grade-level academic content standards (or alternate academic standards for students with the most significant cognitive disabilities). The purpose of these goals is to require educational institutions to provide challenging instruction and to hold high expectations for students with disabilities. This is intended to create students who are college or career ready when they transition to adulthood. Parents of students with

disabilities are to be informed of their student's progress as often as are parents of students without disabilities. Therefore, if general education report cards are distributed quarterly, reports on goal progress must also be distributed quarterly. Progress toward reaching annual goals does not necessarily require a letter grade but can be performance based or criterion referenced; it can be rated on a spectrum, such as from "no progress" to "goal met." In addition to goals, students who participate in alternative assessments require benchmarks that delineate smaller steps needed to meet the goal (Assistance to States for the Education of Children with Disabilities, 2017).

Example Goals and Benchmarks As an example, a goal for a student named Sally might be, "While participating in a classroom activity, Sally will make one request to an adult or peer using a core vocabulary word (i.e., words that have a functional and academic purpose) through a preferred mode of communication for four out of five classroom activities" (Goalbook, 2017).

Example Short-Term Objectives/Benchmarks

1. By the first quarter, given an object during a classroom activity and a verbal cue, Sally will indicate that the object is liked or disliked (e.g., by smiling or crying) within 5 seconds for four out of five objects.
2. By the second quarter, when presented with a highly preferred object during a classroom activity, Sally

Table 33.2. Different approaches and environments for providing special education services and the distribution of students within these environments

Environment	% of all students with disabilities	Means of service provision
0%–20% of the day spent in a special education setting	All disabilities: 62% Learning disabilities: 69% Speech-language impairment: 87% Emotional disturbance: 45% Intellectual disability: 16% Other health impairments: 64% Autism: 40%	<i>Co-teaching or general education class with consulting special education teacher or related services provider, services with or without special materials:</i> A special education teacher or related services provider shares responsibility for teaching with the general education teacher in the general education setting or assists the general education teacher in adapting the general education curriculum to best meet the needs of the child with a disability. A special education professional may also come into the classroom to work directly with the child. <i>General education with resource services:</i> The child receives services from a special education teacher and/or related services provider (e.g., physical therapist, occupational therapist, or speech-language pathologist) outside of the general education setting for a small (< 21%) portion of the day.
21%–60% of the day spent in a special education setting	All disabilities: 19% Learning disabilities: 24% Speech-language impairment: 5% Emotional disturbance: 18% Intellectual disability: 27% Other health impairments: 21% Autism: 18%	<i>General education class with resource services:</i> The child typically joins a small group of students in a separate classroom (21%–60% of the school day) to work on areas of need, with a special education teacher and/or related services provider.
61%–100% of the day spent in a special education setting	All disabilities: 14% Learning disabilities: 6% Speech-language impairment: 4% Emotional disturbance: 20% Intellectual disability: 49% Other health impairments: 10% Autism: 33%	<i>Self-contained environment:</i> The child is educated in a separate special education class for the majority (61%–100%) of the school day but typically has lunch and nonacademic classes with peers without disabilities.
100% of the day spent in a special education setting	All disabilities: 3% Emotional disturbance: 13% Multiple disabilities: 18% Deaf blind: 18%	<i>Separate day school:</i> The child attends a school that serves only children with disabilities, and he or she spends no time during the school day with children without disabilities.
	All disabilities: 0.3%	<i>Separate residential school:</i> The child attends a live-in special education program.
	All disabilities: 0.4%	<i>Hospital or home-bound instruction:</i> The child is unable to attend school and is educated in the hospital during a hospital stay or receives services at home.

Source: U.S. Department of Education, Office of Special Education and Rehabilitative Services (2015).

will independently reach for the object within 3 seconds for four out of five highly preferred objects.

- By the third quarter, when presented with a preferred object during a classroom activity, Sally will request access to the object by using one core vocabulary word with prompting for four out of five communication opportunities (Goalbook, 2017).

The Transition Individualized Educational Program

An adolescent with a disability needs to start preparing for life in the community (see Chapter 40). According to IDEA 2004, the plans for meeting this goal may include preparing for “postsecondary education, vocational training, integrated employment (including supported

employment), competitive employment, continuing and adult education, adult services, independent living, or community participation” (§ 602[30][A]).

Beginning at age 16 (though it is widely recommended to start sooner), a formal transition IEP must be prepared and should be based on the individual student’s needs, interests, and choices. It must include the following:

- The development of appropriate measurable post-secondary goals based upon age-appropriate transition assessments related to training; education; employment; and, where appropriate, independent living skills
- The development of a statement of the transition services (including courses of study) needed to assist the student in reaching those goals

Carter, Trainor, Sun, and Owens (2009) recommend that “postsecondary goals be deeply entrenched in values and beliefs about family, community, adulthood and disability” (p. 76). Transition IEPs should be culturally responsive. A transition IEP will map out “instruction, related services, community experiences, the development of employment and other post-school adult living objectives, and, when appropriate, acquisition of daily living skills and functional vocational evaluation” (§ 602[30][C]).

TREATMENT, MANAGEMENT, AND INTERVENTIONS

Multitiered Systems of Support

Multitiered systems of support (MTSS) is a systematic method of delivering increasingly more intensive levels of academic instruction or social/behavioral instruction/support for all students based on need. In this way, struggling students are able to grow academically and behaviorally without the need for a special education designation. The average age that a student is identified as having a specific learning disability in reading is 10 years (or 4th grade). With MTSS, students receive assistance at a much earlier stage in their educational career. The MTSS process is a schoolwide initiative that begins services in kindergarten. Some student’s academic and behavioral difficulties are resolved through the MTSS process, and those students are able to avoid placement in special education altogether. Support and instruction is delivered in three tiers: 1) universal, 2) targeted instruction, and 3) intensive interventions. Students who are in Tier 3 and lack progress or students in Tier 3 who require special education levels of service to maintain gains likely need a special education evaluation to determine if they have an identifiable disability. The student’s level of progress during tiered instruction is one method that can be used to identify a specific learning disability. MTSS is divided into two systems. The academic segment of MTSS is referred to as response to intervention (RTI). The social/behavioral segment is referred to as positive behavior interventions and supports (PBIS). See Figure 33.2.

Response to Intervention RTI generally includes “universal screening, a high-quality core reading [or other academic] program, progress monitoring, increasingly intensive tiers of intervention, and fidelity of implementation” (Otaiba, Wagner, & Miller, 2014, p. 130).

As with both MTSS systems, RTI is a three-tier model. About 80%–85% of students fall into Tier 1

(universal); these are students who respond to the high-quality, research-based instruction provided in the classroom and perform near grade level or above.

About 10%–15% of students are serviced in Tier 2 (targeted instruction); these are students performing below grade level. Tier 2 students are provided with research-based, small-group instruction in deficit areas in addition to the instruction they receive in the classroom. With this additional instruction, they make progress at a rate that will allow them to catch up with their peers. Some Tier 2 students gain the requisite skills that they were lacking and no longer require additional instruction; these students return to Tier 1. Some Tier 2 students make appropriate progress but require additional instruction to continue their gains; these students remain in Tier 2.

About 5% of students do not progress at a rate that allows them to approximate typical student performance, even with Tier 2 interventions. These students require more intensive services and move to Tier 3 (intensive intervention). In Tier 3, students receive smaller group or individual instruction targeted to meet their unique areas of weakness in addition to the services they receive in Tiers 1 and 2 (Otaiba et al., 2014; Procter, Graves, & Esch, 2012).

RTI also concerns the identification of students with specific learning disabilities (SLD). RTI, in fact, was introduced by IDEA 2004 as an alternate and preferred method for identifying students with SLD.

The Institute of Education Sciences conducted a national study in 2011–2012 of the effectiveness on RTI. The study found that RTI was not an effective intervention; however, this study had serious methodological flaws that call into question its conclusions. For example, the researchers used students who were stronger readers than those who typically receive support, and schools provided small-group instruction to both the experimental and the control group (rather than the typical large-group general education environment). The study also included schools with only one student in the entire school in Tier 2 or 3. Until further research is done, RTI continues to be regarded as an effective intervention for struggling students (Fuchs & Fuchs, 2017; Gersten, Jayanthi, & Dimino, 2017).

Positive Behavioral Interventions and Supports

PBIS includes “key characteristics of (a) school climate, (b) proactive strategies, and (c) systematic, system-wide practices” (Farrell, Collier-Meek, & Pons, 2013, p. 39). It also has three tiers of service. Tier 1 includes explicit teaching of school expectations and routines as well as positive reinforcement (such as tickets that can be turned in for prizes) for following those expectations

Figure 33.2. Multitiered systems of support.

and routines. Approximately 80%–85% of students behave appropriately under these approaches. Tier 2 interventions are used for the 10%–15% of students who are not progressing with universal supports. These include targeted interventions, such as small-group social skills instruction or check-in/check-out with an adult at the beginning and end of each school day. For the 5% of students not responding to Tier 2 supports, the school will initiate Tier 3. Tier 3 intensive interventions may include counseling and/or wraparound services following a functional behavioral assessment (Farrell et al., 2013; McDaniel, Bruhn, & Mitchell, 2015).

Accommodations and Modifications

Students with disabilities can be supported within the general education curriculum in many ways, among which are accommodations and curriculum modifications. **Accommodations** are changes in the way a student has access to the curriculum or demonstrates learning. Accommodations 1) provide equal access to

learning, 2) do not substantially change the instructional level or content, 3) are based on individual strengths and needs, and 4) may vary in intensity or degree. An example of this would be reducing a spelling list that teaches the concept of the *-it* ending from 10 words to 5 words. The student with a disability is responsible for learning the same material as the students without disabilities, although with a reduced output. Other examples include reading directions to the student, providing extended time to complete assignments, providing study aids, giving frequent reminders of rules, using a calculator for solving math word problems, and giving note-taking assistance.

Modifications to curriculum provide material that substantially changes the general education curriculum. An example of this would be requiring less challenging spelling concepts. Here the student is responsible for learning 5 *-it* spelling words, such as *sit*, while his classmates are responsible for learning 10 *-tion* words, such as *conversation*. Modifications should be considered carefully because reducing

expectations for students with disabilities can lessen their chance of being college or career ready upon transition to adulthood.

Curriculum modifications in reading may involve approximations of the grade-level curriculum, such as Hi/Lo readers for students with mild reading disabilities. Hi/Lo readers allow access to high-content literature (e.g., *Gulliver's Travels*) at a reduced reading level. Modification for students with more significant disabilities might include accessing a high school reading curriculum through teacher-created digital reading material that boils down classic texts such as *Romeo and Juliet* to key story elements such as “home, family, communicate, love and fight” (Apitz, Ruppert, Roessler, & Pickett, 2017, p. 171). Curriculum modifications may also include supports that allow a child to participate without academic expectations, such as using a calculator for math calculation problems. In contrast, using a calculator to assist in a word problem, with a learning expectation of choosing the correct operation to use to solve the problem, would be considered an accommodation.

Inclusion Practices

A number of practices have been developed to accomplish the goal of inclusion. Inclusion refers to educating people with disabilities alongside people without disabilities. Inclusive classrooms expose all students to the same high standards using universal design for learning, a method of individualizing instruction by matching the means of representation of materials, action and expression of student product, and encouragement of student engagement. In addition to universal design, the inclusive class provides accommodations, modifications, supplementary supports, and collaboration with the special education staff for special needs students (Fuchs et al., 2015).

Co-Teaching

As a co-teacher, the special educator shares the classroom with a general education teacher. The two teachers take joint responsibility for all the students in the class regardless of ability. Co-teaching may take many forms: one teach/one assist, one teach/one observe, station teaching, parallel teaching, alternative teaching, or team teaching (Strieker, Gills, & Zong, 2013). Although not the most effective form, the “one-teach/one-assist” model is the most commonly used approach. Here, while one teacher teaches the entire class, the other helps any students in need. Studies have shown that the most effective method of co-teaching is “team

teaching,” yet there are barriers to this approach that include poor communication, lack of planning time, and the special education teacher’s lack of content mastery (e.g., may not be well trained in math instruction). Solutions to these problems include using technology (such as a shared Google Docs or Dropbox account for lesson planning), active listening, depersonalization, and enhanced communication. The special education teacher might also use self-learning such as the Khan Academy to gain mastery of unfamiliar general education content (Scruggs & Mastropieri, 2017).

High-Leverage Practices in Special Education

The Council for Exceptional Children (2011) has created recommended practices for all special educators in Grades K–12. These 22 high-leverage practices include four aspects of practice: collaboration, assessment, social-emotional-behavioral practices, and instruction. *Collaboration practices* include the following:

- Collaborating with professionals to increase student success
- Collaborating with families to support student learning and secure needed services

Assessment practices include:

- Interpreting and communicating assessment information to stakeholders in order to collaboratively design and implement educational programs
- Using student assessment data to analyze instructional practices and make necessary adjustments

Social/emotional/behavioral practices include:

- Establishing a consistent, organized, and respectful learning environment
- Teaching social behaviors

Instruction practices include:

- Teaching cognitive and metacognitive strategies to support learning and independence
- Providing scaffolded supports
- Teaching students to maintain and generalize new learning across time and settings
- Providing positive and constructive feedback to guide students’ learning and behavior
- Using explicit instruction
- Adapting tasks and materials for specific learning goals (McLeskey et al., 2017)

SERVICES PROVIDED BY SPECIAL EDUCATION TEACHERS

Special education teachers provide individualized instruction, supplementary aids, and support designed to meet the needs of students with disabilities. The special education teacher's mission is to instruct and support the student so he or she is able to access the curriculum, benefit from educational instruction, and be college or career ready. Students with disabilities receive the majority of special education services they need from special education teachers, with the remainder of services being provided by related service professionals (as discussed in the section titled Related Services within Special Education). Special education teachers spend the majority of their time directly instructing students with disabilities. The balance of their time is spent creating, adapting, and modifying educational materials; maintaining IDEA documentation; and collaborating with general education teachers (Vannest & Hagan-Burke, 2010). As the IEP manager, the special education teacher is responsible for leading the team in developing the IEP in accordance with the student's needs and the family's input. The special educator also is responsible for assuring that the IEP, once developed, is followed with integrity by the general education staff, paraprofessionals, and related service providers.

Most importantly, special educators are responsible for the direct teaching of academic and functional skills and for providing behavioral supports. In academics, they teach the same material or content (except for students with severe impairments) as is taught in the general education curriculum. However, they provide accommodations and modifications that allow the student to access the material at his or her appropriate instructional level or mode of communication. Even for students with cognitive impairments, academic material can be approximated as an essential skill. As an example, a third-grade core reading skill, "Describe characters in a story (e.g., their traits, motivations, or feelings) and explain how their actions contribute to the sequence of events," can be modified to the essential skill of "Identify the feelings of characters in a story" (Dynamic Learning Maps Alternate Assessment Consortium, 2012, p. 47). Functional skills include daily living skills, social/communicative skills, vocational skills, and/or participation in the community.

THE ROLE OF THE SPECIAL EDUCATION TEACHER IN THE GENERAL EDUCATION CURRICULUM

Although in the past the special educator's role in general education was to support inclusion (for students

who qualify for special education services during instruction in the general education classroom), that role is changing. As special education and general education services become more inclusive (see the section titled Response to Intervention), the role of the special educator becomes more complex. Looking to the future, the special educator likely will fill the following roles, as described by Hoover and Patton (2008):

1. Data-driven decision maker
2. Implementer of evidence-based interventions
3. Differentiator of instruction
4. Implementer of socioemotional and behavioral supports
5. Collaborator

The special educator should also be prepared to supervise paraprofessionals and function as a co-teacher in the general education setting.

The Special Education Teacher as Data-Based Decision Maker

Special educators serve as members of problem-solving teams for at-risk students and students with disabilities. The team interprets teacher-generated data to evaluate the amount of progress students are making. The team uses the data to make decisions about the need for instructional changes (Kovaleski & Pedersen, 2009).

The Special Education Teacher as Implementer of Evidence-Based Interventions

Evidence-based interventions are teaching methods that scientific studies have indicated are the most effective. Their use is imperative when working with students with disabilities. Students are identified with educational disabilities because they have not learned effectively when taught with typical instructional methods (Cook, Tankersley, & Landrum, 2009). Commercial evidence-based interventions can be found on the What Works Clearinghouse web site of the U.S. Department of Education (<https://ies.ed.gov/ncee/wwc/>). The National Center on Intensive Intervention (<https://intensiveintervention.org/>) provides data-based instructional techniques and interventions to improve outcomes in students with severe and persistent learning and behavior needs. Information about noncommercial evidence-based practices can be found in educational research journals. As an example, publications of the Council for Exceptional Children

(a professional organization for special education professionals; <https://www.cec.sped.org/>) are valuable resources for finding evidence-based interventions.

The Special Education Teacher as Differentiator of Instruction

Differentiated instruction means that the teacher structures instruction to best fit the needs of each student. Instruction can be differentiated in the following areas (Watts-Taffee et al., 2013)

- Content (altering complexity or presentation)
- Process (altering the amount of support as necessary)
- Products (varying methods of demonstrating mastery)
- Learning environment (the physical structure of the room, established learning routines, and culturally inclusive materials)

The Special Education Teacher as Implementer and Facilitator of Social-Emotional and Behavioral Supports

Special educators provide social-emotional and behavioral supports to students through social skills instruction and many other positive behavioral supports and interventions. Social skills instruction can be taught discretely with programs that break down social skills into steps and engage the students in role play. Most programs also have a homework component (the students practice the skill independently) and a self-monitoring component. Examples of such programs include *Skill Streaming* (McGinnis, 2012) and *The Tough Kids Social Skills Book* (Sheridan, 2010). Social skills can be taught during literacy lessons by incorporating books containing social conflicts or the use of prosocial strategies. In addition to supporting their own students, special educators often serve on schoolwide positive behavior support teams, which provide and monitor schoolwide programs intended to decrease interfering and bullying behaviors.

The Special Education Teacher as Collaborator

As a collaborator, the special education teacher must familiarize the general education teacher with the adaptations and modifications necessary to enable the student to benefit from inclusion. The two teachers then discuss who will be responsible for each aspect of the student's instructional needs. For a student

who needs only limited support, the special education teacher might provide content enhancements such as the use of graphic organizers, study guides, or visual displays (Jitendra, Burgess, & Gajria, 2011). The special educator may create adapted tests or check on the student at the end of the day to confirm that all of the homework assignments have been written down. For a student who needs more extensive support, the special education teacher may supply modified assignments that cover the same content as the general education lesson but that are at the student's academic level (see the section titled "Accommodations and Modifications").

The Special Education Teacher as Supervisor of Paraprofessionals

As a supervisor, the special education teacher is responsible for assessing the level of service delivered to students by paraprofessionals. Teachers need to actively manage paraprofessional support by creating a job description so that expectations are clear. Paraprofessionals help provide services but should not engage in instruction, assessment, long-term planning, collaborating and consulting with general educators, or supervising other paraprofessionals. These tasks are the job of the special education teacher. The special education teacher can best maintain quality paraprofessional support by conducting frequent, brief observations with both verbal and written feedback of performance (Douglas, Chapin, & Nolan, 2016; French, 2001). See Box 33.2 for more on special education teachers.

THE SCHOOL-PARENT CONNECTION

One of the keys to positive results for students with disabilities is the teamwork between the school and the family. Educators only see one facet of a student's abilities—his or her performance at school. Parents, conversely, see the whole student. For example, a parent might know of a special interest or enjoyable activity that the educator might provide as a motivator for the student's school performance. Goals and placements also need to be decided jointly by the parents and the special education team. It is encouraging to note that parent attendance at IEP meetings is strong. A federal longitudinal study (the Special Education Elementary Longitudinal Study [SEELS]) found that 90% of parents of students with disabilities attended their students' IEP meeting (SRI International, 2007).

The close partnership between special educators and parents has another direct benefit; the parents understand and appreciate the efforts being

BOX 33.2 EVIDENCE-BASED PRACTICE**Attrition Rates of Special Education Teachers**

Rates of attrition among special education teachers remain a perennial concern. Special educators leave the field annually at twice the rate of their general education peers (25% vs. 13%). In addition, teacher burnout has been found to have effects that go beyond the problem of filling classrooms with qualified teachers—it also negatively affects students with disabilities who are working to achieve their goals. Wong, Ruble, Yu, and McGrew (2017) found that high levels of burnout (i.e., a low sense of personal accomplishment directly and emotional exhaustion and depersonalization indirectly) were correlated with lower individualized education program outcomes.

made for their students. SEELS found that 91% of parents believed that IEP goals were challenging and appropriate (SRI International, 2007). In addition, the National Longitudinal Study–2 (NLTS-2) Wave 4 (National Center on Secondary Education and Transition, 2009a) reported that 90% of secondary school parents were satisfied with their student’s special education experience.

OUTCOMES

The number of students with disabilities who have graduated from high school increased from 56% in 2006 to 66% in 2016 (National Center for Educational Statistics, 2017). However, many of these students are graduating with alternative diplomas or standards that do not make them college or career ready. Examples of alternative diplomas include certificates for completion, attainment, and attendance or vocational diplomas such as in career or technical education. Some diplomas are granted upon meeting IEP goals (Achieve-National Center on Educational Outcomes, 2016). In addition, although increasing, the 66% rate of graduation among students with disabilities still compares poorly with the 83% graduation rate among their typically developing peers.

Although graduation rates are an important indicator of positive educational outcomes, for many students with disabilities, outcomes are more adequately represented through other means. The NLTS-2 (National Center on Secondary Education and Transition, 2009b) surveyed outcomes of young adults with disabilities in many areas. As an example, 83% liked their job very much or fairly well. Unfortunately, at the time of this writing, the unemployment rate for people with disabilities was 10.5% compared with 4.6% for that of people without disabilities (Department of Labor, 2017). One of the goals of education is to provide students

with the tools they need to succeed in life. Individuals who have benefited from their education should feel positively about their future. Table 33.3 represents the percentage of students who feel hopeful about their future, broken down by disability. The results are positive, with over half of students with a wide range of disabilities indicating that they are hopeful about the future a lot or all of the time.

SUMMARY

- Special education and related services are instruction and supplementary supports that are specifically designed to meet the unique educational needs of a student with a disability. These services are mandated by federal law and are provided by special education teachers and related service providers to students with defined disabilities.
- The IEP provides documentation of instruction and support for a student with a disability including goals, accommodations, and modifications. Services are provided within the framework of LRE.
- IDEA 2004 is the federal legislation that describes identification and provision of services for students with disabilities. Section 504 legislation provides coverage for the wider array of students with disabilities who do not qualify under the stricter guidelines of IDEA.
- The MTSS is comprised of three tiered levels of academic and social interventions that support both students with and without an identified disability.
- Special education teachers perform multiple roles, including a data-driven decision maker, an implementer of evidence-based interventions, a differentiator of instruction, an implementer of socioemotional and behavioral supports, and a collaborator.

Table 33.3. How often youth felt hopeful about the future (Item np2V2d): Overall and by primary disability category

	Total	Learning disability	Speech impairment	Mental retardation	Emotional disturbance	Hearing impairment	Visual impairment	Orthopedic impairment	Other health impairment	Autism	Traumatic brain injury	Multiple disabilities	Deaf/blindness
(1) Never or rarely	14.7%	13.7%	14.5%	22.5%	15.0%	7.2%	4.3%	8.4%	9.6%	17.1%	16.8%	20.5%	7.5%
(2) Sometimes	22.7%	19.5%	30.4%	23.5%	31.1%	23.7%	16.5%	24.3%	25.7%	26.1%	17.7%	16.8%	18.4%
(3) A lot of the time	19.3%	20.8%	19.8%	16.0%	15.4%	28.0%	29.7%	15.0%	14.9%	22.7%	24.6%	14.4%	30.1%

CHAPTER 34

Behavioral Therapy

Henry S. Roane, William E. Sullivan, Brian K. Martens,
and Michael E. Kelley

Upon completion of this chapter, the reader will

- Describe operant conditioning and its relation to behavioral treatments
- Explain the basic principles underlying behavioral processes
- Understand response measurement and data collection as applied to behaviorally based assessments and treatments
- Identify key components of operational definitions for defining target behaviors and developing a data collection system
- Describe the logical underpinnings of single-case experimental designs and visual inspection of single-case data
- Differentiate among the various types of functional assessments
- Explain the types of behavioral treatments appropriate for challenging behavior exhibited by children with developmental disabilities
- Identify the principal concepts and strategies of behavioral skill instruction for teaching a functional communication response to children with developmental disabilities

This chapter addresses the use of behavioral treatments with children with developmental disabilities. Behavioral treatments for this population are part of a broader group of treatments commonly referred to as “behavioral therapy.” All behaviorally based treatments share some core features, such as the use of reinforcement and a focus on environmental determinants of behavior (e.g., antecedents and consequences; Benson, 2016). The focus of this chapter is not on providing an overarching review of behavioral therapy; rather, it describes the appropriate use of behavioral treatments

to address behaviors common among children with developmental disabilities.

In particular, this chapter explains the use of behavioral therapy to address two broad areas of functioning that are commonly targeted in this population: challenging behavior and skill development. For example, Dominick, Davis, Lainhart, Tager-Flusberg, and Folstein (2007) surveyed parents concerning the presence of challenging behavior (i.e., atypical eating or sleeping, aggression, self-injury, and tantrums) in a sample of 67 children with autism spectrum disorder

(ASD) and found that 98% of the parents sampled reported at least one type of challenging behavior. By definition, developmental disabilities involve deficits in adaptive and self-help functioning, including academic behavior, thus highlighting the importance of behavioral treatments for skill development. Moreover, the extant literature has consistently shown that behavioral therapies are effective in addressing these concerns (Heyvaert, Saenen, Campbell, Maes, & Onghena, 2014; Roane, Fisher, & Carr, 2016).

This chapter also distinguishes among behavioral treatments to address the phenotypic expression of developmental disabilities and applied behavior analysis (ABA), a specific form of behavioral intervention for ASD. The behavioral treatments discussed herein share a number of common features with ABA therapy, and a discussion of similarities and specific uses for ABA in relation to behavioral therapies can be found elsewhere (Fisher & Zangrillo, 2015; Roane et al., 2016). Thus, while this chapter focuses on the application of behavior analytic principles to the treatment and remediation of behaviors displayed by individuals with developmental disabilities, it does not focus exclusively on ABA as treatment for ASD.

Although the focus of this chapter is on challenging behavior and skill development, behaviorally based treatments can and are often applied to other issues confronted by children with developmental disabilities. In fact, there are a number of studies that describe the use of behavioral therapies, in particular the use of cognitive-behavioral therapy (CBT), for a range of issues encountered by this population. CBT describes psychotherapeutic approaches that posit a malleable relationship among an individual's cognitions, behaviors, and emotions. As such, CBT incorporates a number of strategies aimed to help the individual become aware of their own dysfunctional thoughts, emotional reactions, and maladaptive behavior patterns. Likewise, CBT challenges the individual to analyze and modify problematic thinking and behavior patterns, as well as to adopt alternative ways of perceiving and responding to their environment. Typically, CBT is a short-term intervention that consists of 10–12 sessions of 1 hour per week. Given the brevity of this approach, CBT does not aim to eliminate all challenging or maladaptive behaviors; instead, CBT equips the individual with the tools necessary to continue therapeutic work on their own.

The use of CBT has become increasingly popular, and many CBT programs are considered evidence based in the treatment of a variety of mental health disorders in both adults and children. For example, the National Institute for Clinical Excellence (2011) in the United Kingdom has recommended CBT as the primary treatment for anxiety disorders. However,

when discussing the use of CBT with individuals with developmental delays and intellectual disabilities, the collective findings have been mixed. To illustrate this point, Lang, Mahoney, Zein, Delaune, and Amidon (2011) and Lang et al. (2010) conducted two systematic reviews looking at the use of CBT to treat anxiety in individuals diagnosed with ASD. The findings indicated that CBT was effective for individuals with ASD that do not have a comorbid intellectual disability, yet for those with an intellectual disability, CBT had little to no evidence.

Generally speaking, when CBT has been implemented in the pediatric populations, the protocols have been adapted to accommodate the child's unique needs, such as 1) simplifying language, 2) incorporating visual cues, 3) relying on less sophisticated cognitive techniques, 4) increasing the use of positive reinforcement, and 5) incorporating caregivers into treatment. This programmatic adaptation illustrates the concept of *flexibility with fidelity* (Kendall & Beidas, 2007; Kendall, Gosch, Furr, & Sood, 2008). To illustrate this point, Beidas et al. (2010) offered a range of suggestions to modify empirically supported treatments such that the individual's developmental needs are considered. This notion is highly relevant when considering a CBT approach for children with developmental disabilities. Nevertheless, at this time, the evidence for CBT to address maladaptive behavior in children with developmental disabilities still falls short of behavior analytic interventions (Sturmey, 2014). Thus, for the purposes of this chapter, the focus will be on behavior analytic treatments to address challenging behavior in children with developmental disabilities.

As noted above, all forms of behavioral treatments share common core features. The first part of this chapter describes some of these principles, as well as operant conditioning, the theory of learning from which they evolved. The following case study serves to illustrate how behavioral therapy is implemented in practice.

■ ■ ■ CASE STUDY

Roger is a 7-year-old boy diagnosed with ASD and moderate intellectual disability. Based on the caregiver report, Roger was delayed in meeting the majority of his developmental milestones (i.e., rolling over, sitting up, crawling, walking, and speaking his first words). At the time of the beginning of a formal behavioral therapy program, Roger was able to communicate using two- to three-word phrases and follow single-step commands.

Academically, Roger struggled across most subject areas but had a relative strength in mathematics. He attended public school and was educated in a special education classroom setting with a one-on-one aide to

support his behavioral needs. When Roger was 4 years old, it was reported that he began to show aggression toward his parents, teachers, and peers when access to preferred items was restricted or when he was asked to complete academic work other than math. Around this same time, Roger began to display self-injurious behavior (SIB) in the form of head hitting, self-scratching, and eye poking. Typically, his caregivers responded to this behavior by 1) reprimanding him (e.g., “It is not okay to hit Mommy!”), 2) removing him from the situation, or 3) giving him his toys back to calm him down. Over time, his behavior worsened and resulted in Roger being admitted into an outpatient clinic that specialized in the treatment of severe maladaptive behavior.

Thought Questions:

How does the three-term contingency (antecedent, behavior, and consequence) apply to the principals of behavioral therapy? How do the different principals of behavioral therapy apply to a response to serious tantrums?

OPERANT CONDITIONING

The common features of behavioral therapy as applied to the concerns of individuals with developmental disabilities initially arose from the research of American psychologist B. F. Skinner (1957). Skinner was heavily influenced by Darwin’s theory of natural selection and applied this theory to understand the manner in which behavior is learned. Specifically, Skinner outlined a process that was referred to as selection by consequences; essentially, behaviors that produce favorable outcomes are likely to persist, whereas behaviors that produce unfavorable outcomes are likely to cease. Thus, the context—or what Skinner referred to as the environment—played a central role in behavior change. For example, in his work with animals (e.g., pigeons and rats), Skinner demonstrated that responses that produced access to food were likely to be repeated and, in many cases, would be completed more rapidly over time.

Skinner’s conceptualization of learning was a novel departure from previous theories (e.g., that all learning was essentially reflexive in nature) in that Skinner posited that an organism’s behavior “operates” on the environment to produce favorable outcomes and decrease unfavorable outcomes. This theory of learning was thus termed *operant conditioning*.

Basic Principles

Operant conditioning gave rise to a number of principles, concepts, and terms that are prevalent in behavioral

therapies for individuals with developmental disabilities. The role of the environment (i.e., the context in which the behavior occurs) was a unique interpretation of how organisms learn. Also, operant conditioning—and by extension, behavioral treatments—conceptualizes behavior by its function (i.e., the purpose it serves) rather than its topography (i.e., what the behavior looks like). This also is a departure from other forms of therapy. In behavioral therapy, treatments are not designed to manage “aggression,” per se (i.e., a topographical distinction of the behavior); instead, treatment is designed to address the function of that behavior (e.g., hitting another person to avoid schoolwork).

Three-Term Contingency

Related to a discussion of function is the notion of the three-term contingency, or the A-B-C contingency. That is, operant behavior consists of three components: 1) the **Antecedent** event that precedes the behavior, 2) the **Behavior** itself, and 3) the **Consequence** that follows the behavior. Using a common example, a phone rings (antecedent), which leads the individual to answer the call and say “Hello.” Saying “hello” (behavior) is reinforced by a conversation beginning with the caller (consequence). Although this is a simplistic example, it illustrates the extent to which the antecedent, the behavior, and the consequence are linked.

Conceptually, the three-term contingency serves as the basis for most behavioral treatments for individuals with developmental disabilities. Determining what events occasion the occurrence of a particular response (i.e., antecedents) and what events typically follow a response (i.e., consequences) can lead to methods of changing the behavior of interest.

Reinforcement

Reinforcement is a process in which the future likelihood of a behavior increases either by 1) presenting a preferred stimulus (i.e., **positive reinforcement**) or 2) removing a nonpreferred stimulus (i.e., **negative reinforcement**) contingent on a behavior. For example, some children might have a tantrum when preferred items are interrupted or removed, and well-meaning caregivers might respond to this behavior by giving the child attention (e.g., hugs to calm them down) or by giving them back their toys. This represents an example of a positive reinforcement contingency in that having a tantrum produces access to preferred events.

An example of a negative reinforcement contingency might be seen in a child who misbehaves when presented with challenging schoolwork. If the child’s

behavior is of such severity that it results in removal of the schoolwork or results in the child being sent out of the classroom, the behavior is negatively reinforced by the removal of nonpreferred activities (i.e., schoolwork). An important distinction to understand is that the process of reinforcement always results in an increase in behavior (hence the term *reinforcer*, which means “to strengthen”). This is the case whether the reinforcement process is intentional or unintentional and whether the reinforcing event is providing access to a desirable event or removing (or avoiding) the presentation of an undesirable event.

Extinction

A related principle is **extinction**, which is a process that decreases the occurrence of a behavior through the discontinuation of reinforcement. Using the previous positive reinforcement example, extinction of tantrums would involve the caregiver no longer attending to the child’s challenging behavior or not providing the child with preferred toys when the child becomes upset. Extinction is a somewhat gradual behavior change process in which learning occurs over time. In the above scenario, the child will eventually learn that tantrums do not “work” to get a desired response from a caregiver, but the tantrums may actually increase transiently as the child tries to make it “work.”

Punishment

Punishment is another process that results in a decrease in behavior. As with reinforcement, punishment is further defined by the presence or absence of a given consequence. Thus, in a positive punishment contingency, behavior results in the presentation of a nonpreferred stimulus. Reprimanding a child is commonly implemented by caregivers as a form of **positive punishment**, meaning the reprimand presented contingent on a behavior is designed to stop that behavior. By contrast, a **negative punishment** contingency is one in which a preferred stimulus is removed contingent upon the occurrence of a behavior. An example of negative punishment could include response cost (e.g., a child throws her toy and her parent then removes the toy for a specific amount of time) or a time-out (e.g., the child is placed in a context in which he cannot access other reinforcers).

Schedule of Reinforcement

Another important principle to consider with the use of reinforcement, extinction, and punishment is the schedule of reinforcement. Simply put, any type of behavior

change occurs most rapidly if the programmed contingency is delivered every time the behavior occurs. This is referred to as a continuous schedule of reinforcement. For example, in this chapter’s opening case study, if Roger’s therapist wanted to teach him to make eye contact, she would immediately and consistently provide praise or access to preferred items every time he made eye contact with her. The use of immediate reinforcement each time the targeted response occurs teaches Roger that there is a positive reinforcement contingency in place for his behavior.

It would be difficult to maintain this level of reinforcement; therefore, to maintain a behavior once it has been acquired, Roger’s therapist would move to an intermittent schedule of reinforcement. For example, she might reinforce eye contact after every three occurrences. In addition to using an intermittent schedule, there are a number of other modifications that can be made to promote response maintenance, including varying the amount of reinforcement, altering the requirement of the target response (e.g., only reinforcing longer durations of eye contact), and increasing the number of responses that must occur before reinforcement is delivered. These parameters are discussed later in this chapter.

An important caveat to schedules of reinforcement is the relative consistency or inconsistency with which a contingency is implemented. For example, a therapist used a continuous schedule of reinforcement to teach Roger eye contact and an intermittent schedule to maintain this response. However, mistakes in the delivery of a contingency can also impact learning. Reinforcement, extinction, and punishment have their most robust effects if they are implemented consistently and immediately once they are first introduced into a behavioral treatment. If they are not implemented in this manner, disruptions in the learning process can occur. For example, if extinction is not implemented in a consistent manner (e.g., some responses are reinforced whereas others are not), the child’s behavior will not decrease as quickly as intended due to unintentional intermittent reinforcement.

Application to Skill Training

The principles of three-term contingency, reinforcement, and extinction are also critical for understanding skill training and academic instruction from a behavioral perspective. Many behaviors are problematic because they occur too often (i.e., as behavioral excesses). Behavioral excesses are already under control of key antecedent stimuli in the child’s environment, have one or more functions or “payoffs” as consequences, and have been learned over time (Martens, Daly, & Ardoyn, 2015).

In contrast, skill deficits are behaviors that have not been learned and therefore do not yet have controlling variables in the child's environment. The goals of skill training and academic instruction are to first bring accurate responding and then fast and accurate responding (e.g., saying, "May I have?") under the control of key stimuli (e.g., a card containing the printed phrase) through the differential reinforcement of correct (but not incorrect) responding in the presence of those stimuli (Martens, Coddington, & Sallade, 2017). That is, reinforcement is provided only for correct responses in the presence of the target stimuli; incorrect responses are placed on extinction to make it clear to the learner what response(s) should be exhibited in the presence of the relevant stimuli. When the child consistently says the correct phrase when shown the card, responding has come under stimulus control of the card.

Stimulus control does not happen all at once but strengthens gradually over time as learners are given opportunities to respond with differential reinforcement, modeling, prompting, and error correction (i.e., training). As training progresses, two types of learning take place: how to perform the behavior correctly (e.g., saying the phrase) and when performance of the behavior will be reinforced (e.g., when the card is present). Early in training, a learner's responding becomes more accurate and eventually efficient as a result of prompting, feedback, and reinforcement. Once the learner can perform a skill accurately with a certain amount of assistance (i.e., prompting and error correction), that assistance is withdrawn or gradually faded until the child can perform the skill accurately and independently. Numerous procedures for systematically fading prompts have been reported in the literature to promote learning with no or few errors (e.g., least-to-most prompting and progressive time delay; Alberto & Troutman, 2017).

At the same time that responding is becoming more accurate, key features of stimuli that control responding are becoming more salient, making them easier to detect across learning trials. For example, as one's completion of math facts increases in accuracy, teacher prompts are faded and the learner's behavior comes under the control of the operation presented (e.g., the "A+" sign). Later in training, when nonessential features of the controlling stimuli are varied (e.g., font of the printed text or the presence of a different caregiver) or their context changes (e.g., a different room), strong stimulus control enables the learner to continue responding correctly (i.e., stimulus generalization). Stimulus control and stimulus generalization are therefore the principal concepts of behavioral skill instruction.

MEASUREMENT AND DATA ANALYSIS IN BEHAVIORAL TREATMENTS

The efficacy of behavioral treatments is typically determined at the level of the individual. In contrast, in many health care and social science research studies, the effects of an intervention are assessed at the level of the group. In assessing these effects, descriptive and inferential statistics are employed. However, with most behavioral treatments, the key comparison is not how one group responds relative to another; rather, the variables of interest are changes in the behavior of the individual. To illustrate, in treating Roger's aggression, determining whether a given procedure decreases the amount of aggression he displays relative to no treatment or alternative treatment options would be most instructive. Clinical decision making might be influenced by the literature conducted with groups, but the outcomes are specific to Roger.

Given that behavioral treatments focus on behavior change at the level of the individual, it is important to understand how the effects of an intervention are determined. As noted, behavioral treatments typically differ from group comparisons in this regard. One such difference is the focus of the behavioral treatment. That is, behavioral treatments typically target a particular behavior that can be directly observed. Although these treatments might use indirect measures (e.g., behavior rating scales) as an adjunct measure in determining program effects, the quantification and measurement of client behavior is paramount.

Target Behaviors and Operational Definitions

One of the first steps in behavioral treatment is to determine what behavior will be addressed. The behavior of interest is referred to as the **target behavior**, and the identification of the target behavior is usually determined by the individual, the respective caregivers, and/or other stakeholders in the individual's life. For example, Roger initially was referred to a specialized outpatient clinic for severe aggressive outbursts. Through consultation with his parents and his school, it was determined that his aggression would be the target behavior.

The next step is to define the target behavior. This is an important step because it helps to ensure that all subsequent data collection will address a specific form of the behavior, thereby ensuring consistency across all aspects of behavioral treatment. Thus, an operational definition is developed to quantify the behavior(s) that will be addressed through treatment. Generally, observational definitions should be concise and detailed

descriptions that are written in a manner such that anyone who did not know the individual would be able to visualize, imitate, and collect data on the response after reading the definition.

In behavioral treatments, operational definitions focus on observable events. Using Roger as an example, an operational definition for aggression might be “contact between either of Roger’s hands, with an open or closed hand, against any part of another person’s body from at least 6 inches away.” Note that this definition makes no mention of Roger’s internal state (e.g., being “angry”); rather, the focus is simply on what behavior can be observed.

Measurement of Target Behavior

Once an operational definition has been developed, it is important to determine the best procedure to measure the occurrence of the behavior. In behavioral treatments, there are generally four ways to measure behavior: 1) how many times it happens (event recording), 2) how long it lasts (duration recording), 3) whether the behavior occurred during a specific observation (interval recording), and 4) what was the outcome of the behavior (permanent product recording).

Each of these measurement systems is associated with various considerations that are linked to the nature of the target behavior. For example, event recording is best used for behaviors that have a discrete beginning and end, such as taking a frequency count on the number of times Roger displays aggression. By contrast, duration and interval recording are better suited for behaviors that are more continuous. For example, when working on Roger’s academics, the length of time his buttocks remain in contact with the seat of his chair (i.e., in-seat behavior) is of interest. Finally, permanent product data would provide a record of the outcome of a given behavior. For example, clinicians could measure the number of bruises that Roger’s caregivers received from his aggression or the number of math problems that Roger completed in a given teaching session.

Data Collection, Experimental Design, and Data Analysis

Developing an operational definition and determining the appropriate measurement system are the initial steps in developing a behavioral treatment. It is also important to be able to identify the effects of the intervention on an individual level. Here again, behavioral treatments offer a somewhat unique set of procedures to assess intervention effects. Before beginning

a treatment, for example, it is recommended to collect sufficient baseline data such that there is a reference point for the occurrence of behavior in the absence of intervention.

There are several considerations for collecting baseline data (e.g., during what context these data will be collected and by whom), but the emphasis is on obtaining information on the “typical” occurrence of behavior. Consequently, it is often necessary to take repeated measures of behavior (i.e., multiple observation) so that a sufficient sample of behavior is obtained. To illustrate, imagine Roger hits his teacher 11 times during reading instruction. Without a frame of reference, it is not possible to determine whether this is a relative improvement or worsening of his behavior. By contrast, if data from reading instruction were gathered over the course of 3 days, revealing 11, 10, and 13 occurrences of aggression, respectively, the clinician has a better understanding of the relative frequency of Roger’s aggression in this context.

The collection of baseline data lends itself to a discussion of experimental designs that are used to examine the efficacy of behavioral treatments. A detailed discussion of single-case research designs is beyond the scope of this chapter but is available from a number of other sources (DeRosa, Sullivan, Roane, & Kadey, in press; Kratochwill & Levin, 2015; Perone & Hursh, 2013). Regardless of the design employed, the primary purpose of the single-case design is to demonstrate that implementation of the independent variable (e.g., intervention) is responsible for the change in the dependent variable (e.g., target behavior). This demonstration is also referred to as showing a functional relation.

The demonstration of a functional relation between treatment implementation and behavior change is often determined through the use of visual inspection strategies. Visual inspection is the process of analyzing data in accord with various changes across treatment and nontreatment conditions or when comparing multiple treatments. To do so, data on the target behavior are plotted on an x - y ordinate graph so that clinically relevant changes across conditions are readily apparent. These data also serve a predictive function; that is, data plotted for visual inspection should reveal consistent response patterns (assuming effective intervention) so that one can predict a continuation of the behavior pattern with the ongoing implementation of treatment. Alternatively, one could predict behavior change if the intervention were terminated. There are multiple resources available that discuss the critical elements of visual inspection (Bourret & Pietras, 2013; DeRosa et al., in press), the relation between visual inspection and statistical analyses (Baron & Perone, 1998), and methods to

enhance reliable visual inspection across multiple clinicians (Fisher, Kelley, & Lomas, 2003; Kahng et al., 2010; Roane, Fisher, Kelley, Mevers, & Bouxsein, 2013).

Thus far, this chapter has covered a number of issues related to basic operant principles, measurement of behavior, and data analysis. Obviously, there are a number of other variables that influence learning and the extent to which behavioral treatments are developed and their effects determined. However, the material noted above serves as the underpinnings to most behavioral treatments for individuals with developmental disabilities. The following sections describe how these basic principles, in concert with other procedures, form the basis of the treatment for challenging behavior and skill acquisition in children with developmental disabilities.

BEHAVIORAL TREATMENT OF CHALLENGING BEHAVIOR

Understanding the role of the environment and the influence of various operant reinforcement contingencies is critical to the development of effective behavioral treatments. Therefore, it is important for a clinician to understand the relative influence of these events on the target behavior. The primary way for determining those relations is through a process called functional assessment.

Assessment of Challenging Behavior

As discussed earlier in this chapter, behavioral treatments address the function of behavior rather than its topography; that is, behavioral treatments are generally developed to address the “purpose” that is served by that target behavior. In 1977, Carr published a seminal paper that described an operant model of SIB that has proven to have application across a wide range of behaviors displayed by individuals with developmental disabilities. Carr’s model posited that SIB occurs because it produces outcomes that increase its future likelihood—that is, it occurs because there is a reinforcement contingency in place. Of course, these contingencies typically develop incidentally and over the course of time.

Consider Roger’s history of SIB. A well-meaning caregiver might hug or hold Roger during episodes of SIB to either comfort him or prevent the behavior from occurring. Although this might result in a brief termination or decrease in SIB, the ultimate effect of this is that SIB develops a history of producing specific caregiver reactions, which could function to strengthen the behavior through positive reinforcement. A similar

scenario could emerge through a child who engages in disruptive behavior (e.g., breaking pencils) when non-preferred academic material is presented (i.e., negative reinforcement). Carr proposed that some SIB was reinforced by the internal stimulation that it produces or attenuates, which was referred to as a self-stimulatory or automatic reinforcement hypothesis.

Functional assessments are procedures designed to gather information, generate hypotheses about behavioral function, and determine the causal factors contributing to behavior issues. To date, three categories of functional assessments have been presented in the literature:

- **Indirect assessment** (Kelley, LaRue, Roane, & Gadaire, 2011) describes assessment procedures that are removed in time and place from the occurrence of the challenging behavior. Relevant procedures include interviews; rating scales; and open-ended, question-and-answer forms.
- **Descriptive assessment** (Martens, DiGennaro, Reed, Szczech, & Rosenthal, 2008) involves direct observation of a target behavior in a relevant setting and data collection on the relevant environmental conditions and target behavior. Although these conditions are fairly unstructured, descriptive assessment involves the direct observation of the target behavior across a variety of contexts (typically in the individual’s natural environment), with little to no direct influence over the contingencies that might be impacting the occurrence of the behavior.
- **Functional analysis** (also referred to as an experimental functional assessment) is based on the procedures described by Iwata, Dorsey, Slifer, Bauman, and Richman (1994) and includes the experimental manipulation of environmental variables that putatively influence the occurrence of the target behavior.

The following sections explain each category of functional assessment in more detail.

Indirect Assessment Indirect assessment (Kelley et al., 2011) is a commonly used, eclectic group of procedures employed to quickly and efficiently gather information about a challenging behavior. Indirect assessment may include an initial evaluation in which a therapist gathers demographic information, including the chief areas of complaint. Next, a client may complete a form, on behalf of oneself or another, answering a series of questions, such as ranking the severity of symptoms of ADHD (i.e., by using Conners’ rating scales; Conners, 2008). Other scales may

provide alternative ratings for statements, such as “My child engages in much more challenging behavior than would be normal in a school.” The scale might include a range of potential answers, such as 1) strongly disagree, 2) somewhat disagree, 3) neither agree nor disagree, 4) somewhat agree, and 5) strongly agree. Scoring the ratings can help draw conclusions about why the challenging behavior occurs.

O'Neill and colleagues (1997) developed a comprehensive indirect assessment system, called the Functional Analysis Interview (FAI). It is a structured interview that includes 11 sections that purport to quickly identify putative functions of challenging behavior. The FAI takes approximately 45–90 minutes to finish depending on the amount of information provided by the client. The interview provides a guide for the interviewer across multiple content areas: 1) developing a description of the behavior; 2) identifying settings events, antecedents, and consequences for maladaptive behavior; 3) identifying how efficient the maladaptive behavior is, alternative behavior, and communicative ability; 4) identifying reinforcers; and 5) describing the history of previous interventions. After completing the interview procedures, the interviewer determines the operational definitions of challenging behaviors, environments in which the responses occur, antecedent and consequent conditions influencing the behavior, and other information that will help select an intervention.

Descriptive Assessment Descriptive assessment (Castillo et al., 2018; Lerman & Iwata, 1993; Mace & Lalli, 1991; Martens et al., 2008) procedures control for some significant limitations of indirect assessment techniques. First, indirect assessment relies on accurate recall of past events and faithful ratings of those events. Descriptive assessment, on the other hand, focuses on observation of the behavior in vivo and data collection of the target behavior under naturalistic environmental conditions. Second, indirect procedures are removed in time and place from the occurrence of the target behavior. Descriptive assessment allows for real-time observation of behavior while interacting with the environment.

The primary value of descriptive assessment is in aiding the development of operational definitions of a challenging behavior and generating hypotheses about the behavior's function (Lerman & Iwata, 1993). Descriptive assessments provide information about the conditions under which the target behavior does and does not occur and the order in which a series of challenging behaviors occur (e.g., response class hierarchies); most importantly, it lays the foundation for the development of experimental analysis of the putative variables influencing behavior.

Functional Analysis In 1982, Iwata and colleagues operationalized Carr's (1977) hypotheses in a series of test conditions in a procedure called functional analysis. Specifically, they arranged a number of observations designed to experimentally test a specific reinforcement contingency. In the social disapproval (or attention) condition, the researchers ignored the child unless he or she displayed challenging behavior, in which case they provided attention to the child in the form of statements of concern or disapproval (e.g., saying “Stop that”). This condition assessed the role of positive reinforcement in the occurrence of a challenging behavior.

A second condition, academic demand, was conducted in which the researchers presented academics to the child and provided a break from instructions (in the form of removal of the academic material) contingent on the occurrence of the challenging behavior. This condition assessed the influence of negative reinforcement on the behavior.

An alone condition was also conducted in which the researchers observed a child who was alone in a room through an observation window. In this condition, there were no programmed contingencies in place for the challenging behavior (i.e., the researchers did not respond to the occurrence of the behavior). Sustained occurrences of the behavior in this condition would implicate Carr's self-stimulatory or automatic reinforcement account of challenging behaviors.

Finally, a control condition was contrasted with the above conditions. In the control condition, the child 1) had access to preferred items (to reduce the likelihood of automatically reinforced challenging behavior), 2) had access to adult attention (to reduce the likelihood of positively reinforced challenging behavior), and 3) had no academic demands presented (to reduce the likelihood of negatively reinforced challenging behavior). The relative benefit of this type of functional assessment is that the clinician has direct control over the contingencies that are influencing the behavior, which permits a more detailed level of analysis and hypothesis testing (Vollmer, Roane, & Rone, 2012).

The results of the Iwata and colleagues' (1994) investigation revealed differentiated response patterns across participants (i.e., some individuals displayed the challenging behavior in one condition, whereas others did the same in another condition). These results were important because they validated the hypothesis presented by Carr (1977) regarding the potential role of operant contingencies in the occurrence of a challenging behavior. They also indicated that there were idiosyncratic differences regarding the reason that a challenging behavior occurred across participants. The functional analysis procedure developed by Iwata and

colleagues (1994) has been validated in hundreds of studies addressing many different types of challenging behavior (Beavers, Iwata, & Lerman, 2013; Hanley, Iwata, & McCord, 2003). It has also proven to be an adaptable model of assessment, with procedural modifications made to decrease time expenditures (Falconi, Muething, Roberts, Hamrick, & Shpall, 2016), to develop novel conditions (McCord, Thompson, & Iwata, 2001), and to be implemented in nonclinical settings by individuals other than trained researchers (Martens, Gertz, Werder, & Rymanowski, 2010). Moreover, the advent of functional analysis has resulted in an increased use of reinforcement-based treatments for challenging behaviors and a decreased reliance on punishment-based procedures (Didden, Duker, & Korzilius, 1997). See Box 34.1 for more on the evidence base for functional analysis.

Nevertheless, the functional analysis procedure is not appropriate for all populations or settings. Some limitations of this approach include 1) a temporary worsening of behavior because the individual is contacting reinforcement contingencies that increase the occurrence of that behavior, 2) the use of contrived situations that may not be applicable to the individual's

natural environment, and 3) time constraints and necessary expertise in conducting or overseeing the procedure. As a result, a number of alternative procedures have been developed to assess the role of various reinforcement contingencies on the occurrence of challenging behavior (Martens et al., 2008).

Figure 34.1 shows the results of a functional analysis conducted with Roger to identify the reinforcement contingencies that maintained his aggression. A control condition and four test conditions (attention, tangible, demand, and ignore) were implemented in a multi-element, single-case design. The control condition (toy play) consisted of a therapist delivering near continuous attention to Roger, in the absence of any instructions, while he had access to preferred toys. The attention condition involved a therapist diverting their attention away from Roger and delivering attention in the form of reprimands ("No Roger, it's not nice to hit other people!") contingent on aggression.

In the demand condition, the therapist delivered academic instructions to Roger, and, contingent on aggression, a brief break was provided. A tangible condition was also implemented to test for positive reinforcement in the form of tangible items (Vollmer,

BOX 34.1 EVIDENCE-BASED PRACTICE

Functional Analysis

Functional assessment has been identified as a "best practice" to developing treatments for severe maladaptive behavior by the American Academy of Pediatrics (Myers & Johnson, 2007). This assessment approach is based on the analog functional analysis procedure developed by Iwata, Dorsey, Slifer, Bauman, and Richman (1994). In a functional analysis, the individual is exposed to a number of "test" conditions. In each of these conditions, the clinician creates a situation that mimics those from the natural environment that might be associated with an increased probability of severe maladaptive behavior. These test conditions are compared with a control condition that is specifically arranged to promote low levels of maladaptive behavior. The child is exposed to a series of direct observations under the various test (and control) conditions. Those conditions associated with the most elevated and persistent occurrences of maladaptive behavior (compared with the control condition) are indicative of a maintaining reinforcement contingency, or the "function" of the behavior. Treatments are then developed that directly address the function of the behavior.

Beavers, Iwata, and Lerman (2013) reviewed more than 400 published studies that had implemented a functional analysis to identify the reinforcement contingencies that maintained challenging or maladaptive behavior. Although most of those studies (approximately 75%) involved children as participants, the methods were also replicated with adult and geriatric populations. Additional generality for this approach was suggested by the use of functional analysis across individuals with and without intellectual and developmental disabilities, and the studies reviewed addressed a large range of challenging behavior types. Across all reviewed studies, Beavers and colleagues found differentiated results (i.e., one or more test conditions being associated with elevated response levels) in over 90% of cases regardless of age, diagnosis, or type of behavior assessed.

Application to Practice

The functional analysis method is effective for identifying the conditions that are most likely to maintain the occurrence of challenging behavior.

Figure 34.1. Results from Roger's functional analysis displaying aggressions per minute across sessions. Each data path represents the corresponding test (attention, demand, tangible, ignore) and control (toy play) conditions.

Marcus, Ringdahl, & Roane, 1995). Here the therapist restricted access to preferred toys and, following the occurrence of aggression, allowed Roger to continue playing with his toys. Lastly, an ignore condition (similar to Iwata et al.'s alone condition) was conducted in which the therapist was present in the room with Roger but refrained from interacting with him regardless of his behavior.

Outcomes from the functional analysis (Figure 34.1) suggested that Roger's aggression was multiply maintained by both negative reinforcement (i.e., escape from academic instructions) and positive reinforcement (i.e., access to preferred tangible items). For the purpose of this discussion, the focus is on treatments developed to address the positive reinforcement function; procedures for addressing multiple functions and combining interventions are discussed elsewhere (Call, Wacker, Ringdahl, & Boelter, 2005; Neidert, Iwata, & Dozier, 2005; Scheithauer, Mevers, Call, & Shresbury, 2017).

In summary, conducting a functional assessment is a valuable first step in developing an effective behavioral treatment for challenging behaviors displayed by individuals with developmental disabilities. In fact, this approach was deemed a best practice by the American Academy of Pediatrics in its practice guidelines for ASD (Myers & Johnson, 2007). The primary benefit of conducting a functional assessment is that it permits one to test specific hypotheses about the potential contingencies that could be affecting the occurrence of a target behavior, thereby determining the function or purpose that the behavior serves. Once known, behavioral treatments can be developed to specifically intervene on that function.

Treatment of Challenging Behavior

The development of a behavioral treatment typically follows the functional assessment. This link between assessment and treatment is important and somewhat unique, in that the functional assessment informs treatment development by providing information on what environmental variables can be altered in treatment. For example, if the functional analysis indicates a negative reinforcement function, we know that the individual is motivated to use a challenging behavior to avoid nonpreferred activities (e.g., completing adaptive living skills). Given this knowledge, the therapist can develop a treatment that provides access to this reinforcer for some other, appropriate form of behavior. The functional assessment identifies which variable(s) to affect in treatment.

Extinction

Following the logic of intervening on the environmental variables that are identified in the functional assessment, a basic component of many behavioral treatments is **extinction**. Technically speaking, extinction involves interruption of an existing relationship between a response and the maintaining reinforcer. Using Roger's positive-reinforcement function (shown in Figure 34.1) as an example, extinction would be arranged such that Roger's aggression no longer produced access to preferred items. Using this procedure, aggression would no longer "pay off" and, over time, the behavior should decrease. All humans encounter extinction periodically. For example, buying a drink from a vending machine could present an opportunity for extinction. That is, if you put money in the machine and pressed a button for your drink of choice, your behavior would be reinforced by delivery of the drink. If, however, the drink does not appear at the bottom of the machine, your drink selection response would have encountered extinction. Over time, you would quit trying to buy a drink from that particular machine.

Extinction is used as a component of many treatments for challenging behaviors displayed by individuals with developmental disabilities. However, it is rarely used in isolation because extinction alone can result in a number of side effects. Consider the vending machine example. If you place your money in the machine, press the button for drink A, and it does not come out, you tend to engage in a number of other responses. For example, you might press the button for drink A again. You might press that same button repeatedly. After a while, you might vary your responding and press the button for drink B, then drink C, and so on. Some people might become angry and hit the machine or swear

aloud. Over time, these behaviors would decrease and you would likely walk away. You might, however, try the machine again the next day or a week later and, if it was still malfunctioning, go through this same series of behaviors. All of these responses are common and are referred to as an **extinction burst**.

When extinction is introduced, there is an increased likelihood of response frequency, response intensity, response variation, and the emergence of emotional behavior or other forms of maladaptive behavior such as aggression. Likewise, the effect of periodically attempting a response that has encountered extinction, such as trying the vending machine after a week, is common and is referred to as **spontaneous recovery**. A review of published data on the use of extinction showed that behaviors resembling an extinction burst only occur in about one third of cases (Lerman & Iwata, 1995).

The potential for extinction bursts is one reason that extinction is rarely implemented as the only component of a behavioral treatment. A second reason is that extinction alone does not permit the development of an alternative response to replace the challenging behavior. Recall the earlier example of using extinction to decrease Roger's aggression. In this case, extinction involved disrupting the relationship between aggression and providing access to preferred activities. That is, Roger's aggression no longer resulted in access to the maintaining reinforcer (access to preferred items). A limitation, however, is that this procedure did not include a mechanism by which Roger could access his preferred activities.

Differential Reinforcement

Differential reinforcement is a broad category of treatments that essentially involve reinforcing behaviors that are alternatives to the challenging behaviors. For example, an individual might be taught to engage in a manual sign to access reinforcement while the challenging behavior is placed on extinction. In Roger's case, this is a treatment procedure by which Roger could access reinforcers.

There are a number of different ways in which a differential reinforcement contingency can be arranged. This section describes three procedures that are used most commonly in the treatment of challenging behaviors for individuals with developmental disabilities: differential reinforcement of other behavior, differential reinforcement of alternative behavior, and differential reinforcement of incompatible behavior.

A **differential reinforcement of other behavior** (DRO) treatment is one in which reinforcement is delivered for the omission of the target behavior for a

period of time. For example, in a DRO treatment, a contingency could be arranged such that Roger's aggression was placed on extinction; however, if he did not engage in aggression for a period of time (e.g., 2 minutes), the reinforcer would be delivered. This procedure teaches the individual that challenging behavior "no longer works" and that not engaging in that behavior produces access to reinforcement. Based on this, when using a DRO, there is not a specific contingency to develop other forms of behavior that might serve as alternatives. Given this, a DRA contingency is a viable alternative.

A **differential reinforcement of alternative behavior** (DRA) treatment is one in which an individual is specifically taught an alternative means of access reinforcement. Recall from Figure 34.1 that Roger had a propensity to engage in maladaptive behavior when presented with schoolwork and self-help tasks (i.e., a negative reinforcement function). A DRA procedure for this contingency might involve placing aggression on extinction and reinforcing compliance with academic work (e.g., completion of a task results in a break from work). Therefore, in a DRA treatment, there is a specific response(s) (i.e., alternative behavior) that produces reinforcement and a specific response(s) (i.e., maladaptive behavior) that does not produce access to reinforcement.

Similar to DRA, a differential reinforcement of incompatible behavior (DRI) treatment is one in which a challenging behavior is placed on extinction and the response that is reinforced is one that is incompatible with that behavior. For example, a DRI treatment for aggression might involve extinction for aggression and reinforcement for the individual holding their hands clasped in their lap. DRI procedures have been used less frequently in the behavioral treatment literature relative to DRO and DRA procedures, but they nonetheless present a viable option for the treatment of challenging behavior in individuals with developmental disabilities.

Functional Communication Training

Children with developmental disabilities often do not imitate or ask for information, may exhibit repetitive or stereotypic behavior, may pay little attention to social cues, and may have limited communication skills (Smith, 2001; Wehmeyer, Brown, Percy, Shogren, & Fung, 2017). As a result, these children may fail to acquire or may be delayed in acquiring key or pivotal skills such as functional communication, object discrimination, imitation, simple speech, self-care, and/or playing with peers. Among these skills, functional communication, or expressing one's wants and needs in socially acceptable ways, is critical for children with

disabilities and has been identified by teachers as essential for kindergarten readiness (Hustedt, Buell, Hallam, & Pinder, 2018; Lin, Lawrence, & Gorrell, 2003).

Functional communication training (FCT) is an extension of the DRA procedure in which the child is taught a specific communication response (or set of responses) to access the same reinforcer that maintained the challenging behavior. This communication response is also referred to as a “mand” since it is used to “command” or ask for the reinforcer (Skinner, 1957). FCT typically occurs in three stages:

1. A functional analysis is conducted to identify the type of reinforcer maintaining the challenging behavior and the antecedent conditions that increase that reinforcer's value as a motivating operation.
2. A low-effort, socially acceptable communication response (e.g., ask, gesture, card touch, switch, or picture exchange) is taught using differential reinforcement along with modeling, prompting, and error correction.
3. Engagement in the communication response is reinforced while engaging in challenging behavior is placed on extinction in the natural environment.

FCT offers several advantages relative to DRA. Specifically, FCT is appropriate for reducing multiple topographies and functions of challenging behaviors and teaches a communication response that is easily recognized by multiple care providers. It is also common in FCT to promote the generalization of communication using multiple trainers and/or common stimuli (e.g., a printed card) and to promote the maintenance of communication by thinning its reinforcement schedule, introducing a delay between communication and obtaining the reinforcer, or increasing the duration of signaled extinction periods when the reinforcer is unavailable for communication (Fuhrman, Fisher, & Greer, 2016).

■ ■ ■ CASE STUDY

Because Roger could follow single-step directions, name objects, and communicate vocally in two- to three-word phrases, his behavioral therapy team decided to incorporate FCT into his treatment program and included several of the elements of FCT described previously. Specifically, they taught Roger to say three different communication “frames” (“May I have?,” “I would like,” and “Can I get?”) when presented with a color-coded script (i.e., script training) using the fading procedure of progressive time delay (Betz, Higbee, Kelley, Sellers, & Pollard, 2011; Brodhead, Higbee, Gerencser, & Akers, 2016).

The color-coded scripts could then be taken by Roger into different settings as common stimuli, thereby promoting generalization of communication. Also using the presence of the color-coded scripts as stimuli, the team promoted the maintenance of communication by decreasing the amount of time during which the scripts were present as signals for the reinforcement of communication using a multiple-schedule approach (Fuhrman et al., 2016; Greer, Fisher, Saini, Owen, & Jones, 2016). A multiple schedule is a procedure in which two discriminative stimuli are used to signal to the individual the various contingencies that are in place during treatment. That is, during periods when one or more of the color-coded scripts were present, communication was reinforced with access to the item. During other times when the color-coded scripts were not present, communication was not reinforced and Roger had to wait to ask for desired items.

During each script training session, the therapist presented a script (e.g., “May I have?”), immediately modeled it by saying the script for Roger, and gave him 5 seconds to repeat the script. If Roger responded correctly on four of five trials, then the delay between presentation of the script and the model was increased by 3 seconds (i.e., progressive time delay). Training continued until Roger responded correctly before the model on four of five trials over two consecutive sessions for each communication frame.

After Roger was able to say each script accurately, the therapist began script fluency training. Five color-coded copies of each script were created and stacked in random order. Roger was told, “Say the card correctly as fast as you can,” and the therapist presented each flash card. Fluency training continued until Roger was no longer able to beat his previous time for saying all 15 flashcard scripts.

Following script acquisition and fluency training, the therapist began teaching Roger to communicate for desired items using the scripts in different situations (i.e., script use). The therapist began each session by placing the corresponding script in front of Roger, displaying a desired item out of reach (e.g., cookie, drink, or toy), and waiting 10 seconds for Roger to use the communication frame to ask for the item. If Roger did not request the item, the therapist prompted a response by saying, “Say the card.” Roger was given access to the item after saying the communication response.

To evaluate the effects of FCT on Roger's challenging behavior, the therapist alternated conditions in which the behavior or communication was reinforced using an ABAB single-case reversal design. She then gradually increased the amount of time in which Roger had to wait to ask for his preferred items. The results of this evaluation are presented in Figure 34.2.

Figure 34.2. Results from Roger's functional communication training (FCT) analysis, displaying aggression (black squares) and functional communication responses (FCR; open squares) per minute across baseline (BL) and FCT sessions. During the multiple-schedule phase, the amount of time before color-coded scripts were presented and FCRs produced reinforcement was gradually increased—that is, i.e., 90 seconds (sec), 120 sec, 180 sec, and 600 sec.

With FCT, it is often necessary to teach an initial form of communication and then expand this repertoire to promote varied responding (see Adami, Falcomata, Muething, & Hoffman, 2017; Brodhead et al., 2016). In this regard, consultation with a speech-language pathologist is helpful (see Box 34.2).

Noncontingent Reinforcement An advantage of FCT is that it teaches a communication response while decreasing the occurrence of challenging behavior.

However, there are some cases in which it might be difficult to teach a communication response or other variables impact a caregiver's ability to respond to the individual's communicative behavior (e.g., a caregiver might not always see a manual sign). In this case, noncontingent reinforcement (NCR) is a viable treatment strategy (see Phillips, Iannaccone, Rooker, & Hagopian, 2017). NCR involves the response-independent delivery of reinforcement based on the passage of time.

Although NCR may seem counterintuitive, the approach is effective because it interrupts the relationship between challenging behavior and reinforcement. For example, an NCR procedure for Roger's aggression might be arranged in which aggression was placed on extinction, but every 5 minutes he received access to his preferred activities for a period of time (e.g., 1 minute). This is a response-independent contingency in that Roger would not have to "do" anything to earn the reinforcer, nor would he have to necessarily forgo aggression in this interval as in a DRO; rather, the reinforcer is delivered "for free" based on the passage of time. The rationale for this is one of affecting his motivation to engage in aggression. That is, if he is receiving reinforcer independently, it should decrease his motivation to use aggression to access reinforcement. The adage, "Why buy the cow if the milk is free?" is applicable.

A benefit of NCR to caregivers might be that the caregiver does not have to acknowledge or wait for the child to emit a response; they simply wait for a signal from a timer. This aspect of NCR may make it feasible for some caregivers. NCR does not, however, teach an alternative response (as does DRA and FCT) or have a

BOX 34.2 INTERDISCIPLINARY CARE

Team Members Contributing to the Development of a Functional Assessment and Behavioral Treatment

Role of the medical professional: Identify underlying physical causes of behavior (e.g., self-injury due to eczema, pica due to iron deficiency), medication management, and assessment of the child relative to developmental norms.

Role of the psychologist: Assess and treat comorbid mental health disorders (e.g., anxiety).

Role of the behavior analyst: Identify environmental variables contributing to and maintaining challenging behavior and develop function-matched treatments for challenging behavior and reinforcement-based, skill-acquisition programs.

Role of the speech-language pathologist: Assist in the identification and teaching of communication responses that could serve as functional alternatives to challenging behavior.

Role of the occupational therapist: Assess sensory processing issues and provide strategies to meet the child's unique sensory needs.

Role of the special educator: Identify teaching modifications (instructional and environmental) to facilitate generalization of treatment and identify strategies to incorporate into the classroom.

Role of the social worker: Identify levels of care (e.g., respite services), coordinate care across multidisciplinary providers, and provide family support.

contingency in place to specifically promote decreases in challenging behavior (as does DRO). In addition, there is some risk that the reinforcer delivery in NCR could be incidentally paired with the occurrence of the challenging behavior (Vollmer, Ringdahl, Roane, & Marcus, 1997).

Punishment The role of punishment as a behavior change procedure has been described above. According to practice standards set by individuals who develop behavioral treatments (Van Houten et al., 1988; Vollmer et al., 2011), punishment procedures should only be used 1) when all other evidence-based treatment avenues have been exhausted, 2) when reinforcement-based procedures alone have proven ineffective, or 3) in conjunction with a reinforcement-based procedure.

The use of punishment procedures in the treatment of challenging behaviors displayed by individuals with developmental disabilities has decreased since the development of the functional analysis procedure (Didden et al., 1997). However, some studies suggest that punishment contingencies are necessary in the treatment of some cases of challenging behavior (Hagopian, Fisher, Sullivan, Acquisto, & LeBlanc, 1998; Newcomb & Hagopian, 2018). Also, whereas early studies on the use of punishment involved highly aversive procedures (Lovaas & Simmons, 1969), there has been a general move toward more negative punishment procedures, such as the use of time-out. Although punishment was not used in the case study concerning Roger, recent research shows that a punishment procedure can be necessary to decrease the occurrence of some behaviors exhibited by individuals with ASD and intellectual disabilities (DeRosa, Roane, Bishop, & Silkowski, 2016). As noted by DeRosa and colleagues, punishment was only considered for that individual after a number of reinforcement-based procedures had been ineffective at reducing the participant's rumination to clinically significant levels; this approach is consistent with practice standards regarding the use of punishment.

Generalization of Behavioral Treatments for Challenging Behaviors

Regardless of the treatment approach, an important focus of behavioral treatments should always be programming the environment to ensure that the treatment contingencies are effective across multiple contexts, caregivers, and settings. Stokes and Baer (1977) described nine strategies of generalization that can be used to help ensure that treatments developed in one setting (e.g., a clinic) or implemented by one individual (e.g., a trained clinician) are equally effective

across other settings and individuals (e.g., a teacher in a school).

One of the primary procedures used to generalize treatment effects involves the incorporation of natural stimuli into the training (or clinical) environment. For example, it is helpful to incorporate materials that the individual encounters in his or her typical environment. This might include using the actual schoolwork presented in the classroom during treatment in a clinic or arranging the clinic environment to more closely resemble the home environment. For example, a clinical setting might be modified by using more naturalistic furniture (e.g., couches) and using confederate staff members to make the environment more closely resemble the home.

An area of obvious importance in programming for treatment generalization is incorporating the individual's caregivers as treatment agents. There are a number of studies that have examined caregiver-training strategies (Lerman, LeBlanc, & Valentino, 2015). Generally speaking, this involves a gradual program in which caregivers first observe a trained clinician implement the treatment procedures. The clinician and caregiver might then role play the procedures while data are collected on the caregiver's implementation of procedures to ensure they meet criterion levels (e.g., 80% accuracy for implementation). The use of immediate and delayed feedback is also helpful when a caregiver is implementing the treatment. Finally, follow-up in the home either in person or through telehealth (Barretto, Wacker, Harding, Lee, & Berg, 2006; Tomlinson, Gore, & McGill, 2018) is beneficial to ensure program fidelity and long-term maintenance.

SUMMARY

- Operant conditioning views behavior as an interaction between the individual and the environment.
- The core principles of operant conditioning (e.g., reinforcement) form the basis of most behavioral treatments.
- Behavior treatments are individualized and are matched to the function of the individual's challenging behavior.
- Data collection is typically personalized through the use of unique operational definitions, and the effects of interventions are analyzed through single-case experimental designs.
- Functional assessment identifies the environmental variables that are associated with the occurrence and maintenance of challenging behaviors.

- Functional assessment can include an indirect assessment, a descriptive assessment, a functional analysis, or a combination of procedures.
- Following the functional assessment, a treatment is developed that includes operating on the variables identified in the functional assessment. These treatments often involve an extinction component, although extinction is seldom used in isolation.
- Reinforcement-based procedures such as DRO, DRA, DRI, FCT, and NCR are often combined with extinction. Punishment procedures are only necessary in a minority of cases.
- A necessary step throughout the treatment process is to incorporate procedures that will enhance the ability of the treatment to be generalized to other settings and caregivers.
- Other related topics include the use of preference assessments to identify stimuli that can be used as positive reinforcers, stimulus control procedures to teach discrimination across various contingencies, and antecedent-based procedures such as picture schedules or rules.
- Behavioral treatments follow a common process—they are based on a systematic assessment process.

CHAPTER 35

Oral Health

Erik Scheifele, Mitali Y. Patel, Anupama Rao Tate,
and H. Barry Waldman

Upon completion of this chapter, the reader will

- Understand the causes of dental caries (decay) and periodontal disease and become familiar with preventive strategies and treatment
- Become aware of the special oral considerations for children with disabilities
- Appreciate the oral health needs during the transition to adulthood
- Understand the value of a medical-dental home

An individual's oral health is an inseparable part of their overall health and well-being (American Academy of Pediatric Dentistry, 2017–2018a). Individuals with intellectual and developmental disabilities (IDD) are more likely to have unmet dental needs and face substantial challenges in accessing both preventive and routine dental services. Poor oral health can affect an individual's ability to eat, sleep, and function pain free, and it may contribute to systemic illness (Norwood & Slayton, 2013). As the oral health care for those children with developmental disabilities requires specialized knowledge, providers must have an increased awareness, attention, adaptation, and methods of accommodation beyond what are considered routine (American Academy of Pediatric Dentistry, 2017–2018b). Disparities that exist in providing oral health care services for this population have become more evident in recent years (Milano, 2017; Petrovic et al., 2016). Barriers to oral health care may be patient centered, provider centered, financial, or educational (Milano, 2017). Educators and clinicians frequently lack knowledge about

the dental needs of children with developmental disabilities, and language, transportation, caregiver beliefs, and cultural beliefs can all affect access to care (American Academy of Pediatric Dentistry, 2017–2018b; see Chapter 41). This chapter focuses on oral health conditions and issues that may be associated with children with IDD.

■ ■ ■ CASE STUDY

Maggie is a 6-year-old girl with Down syndrome who is nonverbal. Her parents believe she is having oral pain but cannot look in her mouth. She has been eating less and rubbing the right side of her face for the past few days. She is now being examined by her pediatrician. Her parents have tried to prepare their daughter for this experience. However, Maggie gyrates her head and is distracted by bright lights and other stimuli in the pediatrician's office, and the clinician struggles to observe her face, lips, and tonsils. She concludes that everything appears to be "within normal limits." Unfortunately, all

too often when it comes to the oral cavity, many pediatricians' examinations tend to be rather cursory, consisting of just a glance at the lips and throat. For most children this sort of examination would be routine and sufficient. Because of the specific risks for dental disease in Down syndrome, however, for Maggie oral-examination procedures warrant special care and the gathering of more information than might be apparent by routine observations. Understanding Maggie's cognitive and functional abilities will help guide communication and instruction at an appropriate level that she can understand. Practices to increase successful interactions include 1) scheduling appointments at the best time of day for the child, 2) minimizing office distractions, 3) providing clear and concise instructions at the appropriate cognitive level, and 4) using tell-show-do instructions to introduce procedures and equipment.

Thought Questions:

What interventions can decrease the development of dental caries? What are ways to enable children with developmental disabilities to receive dental services?

ORAL DEVELOPMENT

Eruption of Teeth

The human face begins growth during the fourth week of embryonic development, with tooth formation originating at approximately 6 weeks of age (Casamassimo, 2013). Although it is commonly said that the first primary tooth should erupt by 6 months of age, the age of eruption actually varies widely, with the first primary tooth coming anywhere between 4 and 17 months of age, while the full complement of primary teeth takes 2–3 years for complete eruption. The first permanent tooth typically emerges around 6 years of age, and most permanent teeth have erupted by 12–13 years of age. Third molars ("wisdom teeth") may erupt between 17–25 years of age.

When a permanent tooth erupts, a primary tooth is usually exfoliated. This does not occur with the first, second, and third permanent molars; however, because they do not have primary teeth counterparts. As noted previously, tooth eruption tables should be evaluated cautiously, especially in children with developmental disabilities, as each child's growth and development is unique. A 6-month discrepancy from the recommended eruption time is not considered unreasonable for any child (Dean, Avery, & McDonald, 2015). Symmetry in eruption and sequence of eruption can be more important than development coinciding with a

conventional time schedule. The order in which teeth eruption occurs is more important to monitor rather than the age at which it occurs. What occurs on the right side should occur within a few months on the left, and what occurs in the mandible (lower jaw) should occur in the maxilla (upper jaw) within a reasonable period of time.

Dental Anomalies

Many genetic syndromes associated with developmental disabilities have characteristic developmental dental anomalies. These could include the presence of extra teeth, congenitally absent teeth, unusually shaped teeth, abnormalities in their mineralization, or delays in eruption. These abnormalities may contribute to **malocclusion** (improper interdigitation or alignment of teeth or jaws) and/or to an increased risk for dental caries and periodontal disease. **Anodontia** (the absence of all teeth) is rare, but **oligodontia** (the absence of one or several teeth) can be seen in children with a number of genetic syndromes including Hallermann-Streiff syndrome, chondroectodermal dysplasia, Williams syndrome, Crouzon syndrome, achondroplasia, incontinentia pigmenti, ectodermal dysplasia, and cleft lip and palate (see Appendix A). Disorders affecting development of teeth may also lead to enamel defects and abnormally shaped teeth or contribute to eruption difficulties, as seen in Cornelia de Lange syndrome (Dean et al., 2015). Dentition anomalies also occur in children with chromosomal disorders such as Down syndrome, in children with inborn errors of metabolism such as mucopolysaccharidoses, and in children with inherited disorders of bone formation such as osteogenesis imperfecta (Dean et al., 2015).

Environmental influences can also affect intra-uterine tooth development. For example, nutritional deficiencies—especially of calcium; phosphorus; and vitamins A, C, and D—may result in generalized enamel **hypoplasia** (underdevelopment of enamel or enamel irregularities), resulting in defective mineralization of the teeth during their development (Dean et al., 2015).

Developmental tooth anomalies can also occur as a result of childhood illness or its treatment. For example, if a developing fetus or child between 4 months and 8 years of age is exposed to the antibiotic tetracycline, the primary or permanent teeth may have yellow, brown, or gray discoloration when they erupt. Traumatic injury to a tooth can cause a white or brown defect on a single tooth, whereas prematurity and very low birthweight as well as chronic diseases (e.g., liver failure or congenital heart disease) can cause

hypoplasia or defects in multiple teeth (Dean et al., 2015). The extent and location of enamel hypoplasia can make teeth more susceptible to caries due to compromised tooth structure.

ORAL DISEASES

There are two basic types of oral disease: dental caries and periodontal disease. Both are usually initiated by specific bacteria and therefore can be considered infectious in nature. In general, they occur more commonly in children with disabilities than in their neurotypical peers.

Dental Caries

Dental caries, often called dental decay or cavities, commonly occurs in children and adolescents and is related to the presence of the bacteria *Streptococcus mutans* and *Lactobacillus acidophilus*. Tooth decay is a multifactorial process that involves the teeth themselves, bacteria, diet, saliva, biofilm, the immune system, biochemistry, and physiology. The “chain of decay” can be seen in Figure 35.1. Bacteria adhering to the teeth break down food, creating acid as a byproduct. The acid damages the integrity of the enamel, and cavitation begins. Tooth breakdown and possible abscess formation can occur when caries is left untreated over a period of time.

Bacteria adhere to the teeth in an organized mass called dental **plaque**. Plaque consists of bacteria, bacterial byproducts, **epithelial** cells (from the linings of the lips and mouth), and food particles (Casamassimo, 2013). When plaque becomes calcified, it is called calculus, or **tartar**. Plaque, as well as unremoved tartar, can cause dental decalcification and decay, inflammation, tenderness, and swelling of the gums. This is an early phase of periodontal disease and can lead to loosening of the teeth. The process of decay is characterized by demineralization of enamel and dentin. From 2011 to 2012, the prevalence of dental caries was found to be 37% in 2–8 year old children (Dye, Thornton-Evans, Li, & Iafolla, 2015); the percentage of children ages 5–19 years with untreated dental caries is about 13% (Centers for Disease Control and Prevention, National Center for Health Statistics, 2018).

Caries risk assessment is a tool that can help providers determine and understand the caries disease process in a child, especially risk and susceptibility. Diet, fluoride exposure, oral microflora (bacteria), and a susceptible host are factors, along with behavioral, social, and cultural influences (American Academy of

Figure 35.1. In the presence of adverse factors, the chain of decay is as follows: Acid formed from the action of bacteria on carbohydrates damages the enamel, leading to cavity formation. If untreated, the decay eventually affects the dentin and pulp layer of the tooth and may lead to abscess formation.

Pediatric Dentistry, 2017–2018a). For young children who are receiving carbohydrate-enriched diets to treat growth and development problems or who require chronic liquid medications that contain sugar, cavities may be rampant. Evidence suggests that the infant formula’s impact on the development of early childhood caries depends on the specific properties of the formula. Until more definitive information is available, children should not be allowed to fall asleep with a nursing bottle containing any liquid other than water. The same principle applies to children who are breastfed. Prolonged breast feeding and falling asleep with the nipple in the mouth can promote decay by acid demineralization. In addition, some cultures’ practice of dipping pacifiers in sweetened solutions increases the risk of cavities.

In considering the role of bacteria in the tooth decay cycle, it is important to note that children acquire cavity-causing bacteria during the early phases of eruption of their first few teeth. They usually contract the bacteria

from their primary caregiver. If that person has a high bacterial count or possesses bacteria that are more efficient in causing cavities, the child is at increased risk for future cavities. Parents can help reduce the risk of bacterial spread by themselves undergoing frequent dental cleanings and restoring carious teeth, thereby reducing their bacterial count.

Periodontal Diseases

Periodontal diseases involve damage to the supporting structures of teeth, such as the **gingiva** (gums) and bony sockets of the teeth. Like caries, gingivitis (the most common and reversible form of periodontal disease) is associated with plaque and specific bacterial organisms. The early signs of periodontal disease involve inflammation and bleeding of the gums; the true impact of these insidious processes can go unrecognized for years. Advanced stages of periodontitis are associated with loss of the bone that supports the tooth. Periodontal disease is caused by both local and systemic factors. Local factors include dental crowding of teeth, poor oral hygiene, dry mouth, and destructive dental habits. Systemic factors include side effects of medications, hormonal alterations, and immune deficiency states. Although the exact cause of this condition is unknown, the overgrowth is generally regarded as an exaggerated response to a local irritant. Overall, gingivitis can be found in up to half of children 4–5 years of age (Casamassimo, 2013). All too often, tooth extraction may be the inevitable solution in cases of advanced periodontal disease and extensive dental decay. Difficulties in patient behavior, the effects of the disability on teeth health, and limited financial resources are some of the variables that lead to the relatively high rate of removal of the teeth in individuals with disabilities.

MALOCCLUSION

Malocclusion can interfere with oral functions such as speech and chewing and can increase the risk of dental caries and periodontal disease. In addition, it can create problems with facial appearance and self-image. Although most malocclusions are minor and require attention only for cosmetic reasons, some may be more severe and debilitating. Individuals with IDD have a higher incidence of malocclusion, with 74% of individuals having a definitive malocclusion (Rada, Bakhsh, & Evans, 2015). In these children, correcting malocclusion by orthodontic therapy to position the teeth properly can also ease routine oral hygiene and thus decrease

the risk of dental disease. New technologies such as digital impressions, clear aligners, and specialty equipment have enhanced orthodontic care; however, behavioral challenges and communication issues have kept many providers from attempting to provide orthodontic treatment even if in a limited form to children with IDD (Rada et al., 2015). Difficulties in the maintenance of adequate oral hygiene, the requirement for more dental chair time, and complications of managing associated medical conditions contribute to limited orthodontic care in this population (Blanck-Lubarsch et al., 2014). Other factors affecting access to orthodontic care include financial coverage, provider reimbursement, and finding qualified and willing providers.

ORAL TRAUMA

Uncontrolled head movements, which are characteristic of individuals with cerebral palsy (CP), are a common cause for dental injuries, as the teeth are bumped against hard objects located in the individual's vicinity. As such, movements are equally common in both genders and do not tend to decrease with age. The pattern of injuries to the teeth in individuals with CP differs from the known pattern in a healthy population. In addition, dental and facial trauma can affect both the primary and permanent dentition. Common causes of trauma include motor vehicle accidents, sports injuries, and falls. When the primary dentition is affected by trauma, the underlying permanent dentition can also be affected. A dental injury to the permanent dentition can necessitate numerous procedures and long-term follow-up. Children with special health care needs have a higher prevalence of traumatic dental injury (Al-Batayneh, Owais, Al-Saydali, & Waldman, 2017). Children with CP, for example, are more susceptible to dental trauma in the anterior teeth due to the associated malocclusion, whereas children with conditions associated with developmental disabilities that include difficulty with motor coordination are at risk for dental trauma related to uncontrolled head movements, abrupt movements, and diminished or absent protective reflexes. Patient cooperation and tolerance for dental procedures, the effect of the IDD on the dental and orofacial structures, and long-term care and prognosis can affect treatment of traumatic dental injuries. Lack of dental awareness among parents/caregivers, difficulties in finding a provider, and financial concerns have been cited as reasons for not seeking traumatic dental care (Al-Batayneh et al., 2017). Consideration of these factors may result in the removal of traumatized teeth rather than preservative treatment.

CONTRIBUTING FACTORS TO ORAL CONDITIONS OF INDIVIDUALS WITH DISABILITIES

Oral health is an inseparable part of general health and well-being. Oral diseases can have a direct and devastating impact on the health and quality of life of those with certain special health care needs. Patients with mental, developmental, or physical disabilities who do not have the ability to assume responsibility for or cooperate with preventive oral health practices are at increased risk for oral diseases throughout their lifetime (American Academy of Pediatric Dentistry, 2017–2018a). It is important to understand and explain the role of teeth in eating, speech, growth and development, and aesthetics to patients and their families. An individual child's limitations in being able to articulate the source of oral pain may make it more difficult to prevent, diagnose, and treat dental disease. The actual treatment may also differ because treatment must be adapted to the individual's physical and or cognitive impairment. Therefore, in managing oral health care in the child with a developmental disability, it is important to consider several factors, which are discussed in the following sections.

Regurgitation

Regurgitation (rumination) is often seen in individuals with moderate to profound intellectual disabilities. Swallowing of food, followed by regurgitation, may lead to indigestion, malnutrition, erosion of teeth, and possibly gastroesophageal reflux disease (see Chapter 29). Dental decay may be associated with regurgitation and pouching or pocketing (between cheeks/lips and gums) an accumulation of food.

Physical Limitations

Physical limitations, as seen in CP for example, may affect an individual's ability to carry out personal care, including tooth brushing, rinsing, and flossing. In addition, involuntary movement can make preventive treatment more difficult for caregivers and dental professionals.

Prescription Medication–Induced Decay

Antibiotics, pain, seizure control, and antihistamine oral medications often have a high sugar concentration to mask the taste, which can increase the risk for bacterial growth, acidic biofilm, and dental decay.

Altered Salivary Flow

Psychotropic medications result in decreased salivary flow. This can cause **xerostomia** (dry mouth), salivary gland infections, possible stone formation, and an increased rate of dental decay. In addition, reduced salivary flow is associated with increased burning/soreness of oral mucosal tissues and with difficulty in chewing, speaking, and swallowing. These all can adversely affect food selection and dietary compliance. As an example, children with cystic fibrosis often have thick ropy saliva, which can increase risk of dental decay (Dean et al., 2015).

Food Rewards

Fruit snacks and candy may meet the immediate need to calm and soothe a child or serve as positive reinforcement for behavior, but when combined with other factors, they may dramatically increase decay rates. Frequent intake of sugar-sweetened beverages is also a potential source of tooth decay.

Fractured and Avulsed Teeth

Damaged dentition, particularly of anterior teeth, is often associated with poor ambulatory skills, a history of trauma (accidental or nonaccidental as with seizures or physical abuse), **pica** (eating nonfood items), and self-injurious behavior. Pica may involve chewing on hard, nonedible objects that tend to fracture teeth. Broken and/or discolored teeth can indicate potential infection and should be documented and referred for treatment. Dental and medical professionals should evaluate and report suspected cases of physical abuse when managing oral trauma.

Soft-Tissue Complications

Seizure medication (especially phenytoin) can cause hypertrophy or overgrowth of the gingiva. This can lead to difficulties in delayed **exfoliation** (losing) of primary or eruption of primary and permanent teeth and to periodontal problems. Gingivitis and periodontal disease are more commonly seen in persons with Down syndrome, perhaps because of an immune deficiency (Dean et al., 2015).

Bruxism

Bruxism, or teeth grinding, usually occurs at night. It can be commonly seen in children with athetoid CP. Continued grinding erodes tooth structure and may

cause sensitivity requiring dental restoration. Temporomandibular joint disorders can be a long-term pathology noted in the adult patient.

PREVENTION OF DENTAL CARIES AND PERIODONTAL DISEASE

Perhaps the most important component of preventing dental decay begins even before a child's birth. Eliminating or reducing the transmission of cavity-causing bacteria from the mother to the child, particularly during the susceptible period of bacterial colonization as the first teeth are erupting, is key to reducing caries risk. Identifying mothers with high levels of dental decay and educating them on the importance of their own oral health can help change their trajectory of the child's oral health (American Academy of Pediatric Dentistry, 2017–2018c). Once the child's teeth have erupted, the tools for preventive dentistry include establishment of a dental home, brushing, flossing, fluoride application and dental sealants when necessary for permanent teeth.

Brushing and Flossing

Brushing with a fluoridated dentifrice twice daily should be emphasized to help prevent decay and gingivitis. Children younger than 6 years generally have not developed the manual dexterity to effectively remove plaque from their teeth. Young children and those who have IDD that impacts oral hygiene should be encouraged to participate in their own oral hygiene; however, adults must take an active role and assume responsibility for cleaning the teeth and gums.

Power tooth brushes are as effective as manual tooth brushes and may be helpful for those children with physical disabilities. When brushing, a small smear of toothpaste with fluoride is advised for children less than 3 years old. Those who are 3–6 years old should use a small, pea-size amount of toothpaste with fluoride. If bubbles and foam from the toothpaste cause a problem for the child or guardian performing the tooth brushing, an alternative to toothpaste would be to use water. Positioning the child in a supine (reclining) position facilitates good vision, access, and head control and will help the adult performing the brushing. The number of successful positions is as unique as the disability with which the child presents (Casamassimo, 2013; Dean et al., 2015).

Flossing should be performed wherever teeth are in contact with each other, as the toothbrush cannot clean in between the teeth. When dexterity or motor

coordination is a problem, floss-holding devices are available and can be used by parents and/or caregivers.

Fluoride

Fluoride makes enamel more resistant to decay and remineralizes incipient carious lesions, making them hard again. Whether present in the municipal water supply, taken as a daily supplement, found in toothpaste, contained in a mouth rinse, or professionally applied, fluoride treatment has been shown to significantly reduce the incidence of dental decay and is an integral part of a preventive program. Studies have demonstrated that fluoride in water can decrease the prevalence of tooth decay by up to 60% (Casamassimo, 2013). Most water filters are charcoal and do not remove fluoride; however, reverse-osmosis home filtration does remove fluoride from water. Bottled water must label its fluoride content if fluoride has been added but not if it is naturally occurring. Based on the child's caries risk, water fluoridation levels, and diet and abilities, specific systemic fluoride supplements may be recommended. It should be noted that excessive systemic fluoride can cause **fluorosis**, a condition in which permanent teeth are discolored or malformed.

Many different fluoride formulations are available, each with specific indicated uses. Some children may benefit from a prescribed fluoride rinse, varnish, paste, or gel that contains higher concentrations of fluoride. Often higher concentrated products, such as fluoride varnish, are applied to reverse the early stages of cavity formation. For children with a high caries risk, varnish applications are recommended every 3 months. Silver diamine fluoride, a professionally applied medicament, can be included as part of a caries management plan for patients for whom traditional restorative treatment is not immediately available.

Diet

In children for whom a diet rich in carbohydrates is medically necessary (e.g., to increase weight gain), the dentist should provide strategies to mitigate the caries risk by altering the frequency of preventive visits (American Academy of Pediatric Dentistry, 2017–2018a). More frequent and intensive oral hygiene regimens may be required. Similarly, children with neuromuscular disorders that result in decreased oral-motor abilities may need an extended period to clear food from their mouths. The increased contact time between teeth and food, especially puréed carbohydrates, places these children at greater risk to develop

cavities. Even for neurotypical children, the consistency, frequency, and timing of snacks contribute to the potential for decay. Snacks that are sticky (not just caramels but also fruit snacks) or get stuck in the grooves of teeth (potato chips, or crackers) and those that are eaten frequently between meals have a high potential for causing dental decay.

Dental Sealants

Sealants consist of a plastic coating that is bonded to the biting surface of molars to prevent decay. A long-term reduction of caries in primary and permanent teeth due to the use of sealants has been well documented (Casamassimo, 2013). Many permanent molars have deep grooves that are difficult to keep clean and would benefit from application of sealants. Sealants are technique sensitive and are most effective after full eruption when the tooth can be isolated from saliva and kept dry during placement.

THE DENTAL HOME

Patients with special health care needs who have a dental home (American Academy of Pediatric Dentistry, 2017–2018d) are more likely to receive appropriate preventive and routine care. Ideally, a dental home should be established no later than 12 months of age. The dental home provides an opportunity to provide anticipatory guidance and implement individualized preventive oral health practices to reduce the child's risk of oral disease. As patients reach adulthood, their oral health care needs may extend beyond the scope of the pediatric dentist's training. At this point, patients should be transitioned to a dentist who is knowledgeable about adult oral health needs and able to manage the unique medical needs of the patient.

SPECIAL ISSUES IN DENTAL CARE FOR CHILDREN WITH SPECIFIC DEVELOPMENTAL DISABILITIES

The basic principles of pediatric dental care and oral health apply to all children; however, developmental disabilities may make every day of oral health care a challenge. There are specific dental care issues related to several common developmental disabilities, including Down syndrome, autism, CP, meningomyelocele (spina bifida), and patients who have a seizure disorder. These are discussed in the following sections.

Down Syndrome

In addition to having an intellectual disability, children with Down syndrome have oral findings that may include mouth breathing, open bite and protruding tongue, fissured lips and tongue, **angular cheilitis** (inflammation of the lips), malformed teeth, **microdontia** (very small teeth), midface **hypoplasia** (underdevelopment), small tooth roots, **supernumerary** (extra) teeth, missing teeth, and dental crowding (Dean et al., 2015; Ghaith, Al Halabi, & Alhashmi, 2017; see Chapter 15). Underdevelopment of the midface, hypotonia, dental anomalies, delayed eruption times, and **ectopic** (abnormally placed) eruption may contribute to the development of malocclusion. The incidence of dental caries is similar to or less than that of the general population (Diéguez-Pérez et al., 2016); however, a high incidence of rapid, destructive periodontal disease is commonly experienced (Dean et al., 2015). Children with Down syndrome also have a higher frequency of bruxism (Diéguez-Pérez et al., 2016). **Attrition** (tooth wear) and dental erosion have also been reported to be higher in these children (Dean et al., 2015). Congenital heart disease may also be present, which places these children at increased risk for bacterial endocarditis that may require antibiotic prophylaxis prior to dental procedures.

Autism Spectrum Disorder

The oral and dental conditions of children with autism spectrum disorder (ASD) are similar to other patients (Gandhi & Klein, 2014). In autism, oral health needs are often dictated by the behavior or level of cooperation by a child with sensory integration issues, how the disorder manifests itself in the child's abilities to care for his or her own dental needs, the risk to teeth of self-injurious behavior, and the impact of restricted food preferences on dental health (see Chapter 18). Dental issues related to pica, bruxism, pocketing, and side effects of medication are of particular concern in these children. Children with ASD tend to "pouch" food instead of swallowing it and may prefer soft and sweetened food, which leads to an increased susceptibility to caries (Dean et al., 2015). In addition, the sugar-based food reinforcers that may often be used in applied behavior analysis therapy increase the risk of dental caries. Limiting foods that generate caries should be a goal as well as using reinforcers that have lower carbohydrate content. Children with ASD have a tendency to adhere to strict routines and may require several visits to acclimate the child to the dental environment (Dean et al., 2015). Oral health management and treatment

planning are improved with a detailed family-centered approach based on parental preferences and concerns, the patient's challenging behaviors, and related comorbidities (Gandhi & Klein, 2014). A multidisciplinary team approach can be devised involving behavioral, protective stabilization, and pharmacologic management techniques (Gandhi & Klein, 2014).

Cerebral Palsy

For children with CP, the more severe the neurological insult, the higher the risk of dental disease (Jan & Jan, 2016; see Chapter 21). CP can affect oral health significantly, resulting in changes to the oro-facial region's structure; it also can influence the development of parafunctional habits, including feeding problems, difficulty maintaining oral hygiene, and barriers to oral care access (Alhashmi, 2017). A higher prevalence of malocclusion is more likely and commonly includes protrusion of the maxillary anterior teeth and abnormal biting of food. Disharmony between oral muscles is considered a primary cause of the malocclusions (Dean et al., 2015). Low tone of the orofacial musculature and forward thrust of the tongue have been linked to malocclusions (Alhashmi, 2017). **Sialorrhea** (drooling) is commonly secondary to mouth opening and/or swallowing difficulties and can lead to aspiration, skin irritation, and articulation difficulties (Alhashmi, 2017). The increased production of saliva may be related to an irritation such as dental caries or a throat infection (Jan & Jan, 2016). Children with CP are predisposed to finger sucking and mouthing habits, and they frequently experience bruxism, particularly those with severe motor and cognitive deficits (Jan & Jan, 2016). The increased tendency for falling due to difficulty in ambulation, the reduced ability of reflexes to protect against a fall, and the frequent protrusion of the maxillary incisors may also increase these children's risk for dental trauma (Dean et al., 2015). Conflicting data have been reported regarding the incidence of dental caries in patients with CP compared with the general population (Diéguez-Pérez et al., 2016). In addition, for children with CP who are fed through gastrostomy tubes, despite receiving limited or no nutrition by mouth, they are still susceptible to reflux of stomach acid as well as plaque and calculus buildup, placing them at increased risk for aspiration problems and oral disease. Another common problem is gastroesophageal reflux disease (MedicineNet, 2016), which affects dental health and results in dental erosions (Jan & Jan, 2016). Children with CP are also at greater risk of 1) having developmental enamel defects (Jan & Jan, 2016), 2) having a

greater frequency of periodontal disease and poor oral hygiene (Alhashmi, 2017; Dean et al., 2015), and 3) developing signs and symptoms of temporomandibular joint disorders (Jan & Jan, 2016). Providers should evaluate each child as an individual and not make assumptions about abilities. Providing dental care in the child's wheelchair or using positioning supports such as pillows or a bean bag in the dental chair will allow the patient to be more comfortable. If brushing teeth after eating is not possible, wiping soft food debris from the mouth using a moistened face cloth or gauze pad provides benefits. In older children, an adapted toothbrush with handle modifications, an electric toothbrush, and floss holders can help maintain good oral hygiene. Involuntary movements and severe bruxism will often make restorative dentistry more difficult; however, empathy and a calm, friendly, professional atmosphere are essential.

Meningomyelocele/Spina Bifida

Individuals with meningomyelocele are at a higher risk for dental caries due to poor oral hygiene, poor nutritional intake, frequent snacking, a carbohydrate-rich diet, and long-term use of sugar-containing medications (Dean et al., 2015; Garg, Utreja, Singh, & Angurana, 2013). The presence of a ventricular shunt in an individual with meningomyelocele and accompanying hydrocephalus may require antibiotic prophylaxis to prevent endocarditis prior to undergoing invasive dental procedures (Garg et al., 2013). As a result of orthopedic deformities, paralysis, genitourinary issues, and associated equipment, a patient might find it difficult to sit in a dental chair throughout an appointment. They may need to be treated in their wheelchair or padded appropriately in the dental chair (Garg & Revankar, 2012). Also, individuals with meningomyelocele have an increased risk of developing an allergic reaction to latex due to repeated exposures and cross-reactive food allergies to foods such as avocados, kiwi fruits, bananas, and chestnuts (Dean et al., 2015). Therefore, proper latex precautions should be taken during all dental appointments and latex-containing dental products should be avoided.

Seizure Disorders

As a result of poor oral hygiene, an increased risk of dental trauma, and side effects of anti-seizure medications, children with seizure disorders may exhibit more dental caries and periodontal issues than their typical peers. Seizure-related injuries and aspiration risk warrant special dental considerations, such as using

fixed prostheses over removable partial appliances (Joshi, Pendyala, Saraf, Choudhari, & Mopagar, 2013). Side effects from anti-seizure medications such as gingival overgrowth, **xerostomia** (dry mouth), and drug interactions may be an issue. Approximately one half of children receiving the anti-seizure medication phenytoin develop gingival overgrowth. Changing or discontinuing the medication may resolve the condition to some degree; however, surgical reduction may be needed (Casamassimo, 2013). Meticulous oral hygiene may prevent or significantly decrease the severity of the condition. Children who suffer from tonic-clonic seizures require special consideration for dental restorations and appliances to prevent the risk of inhalation and damage to appliance and tissues during a seizure (Mehmet, Senem, Sulun, & Humeyra, 2012).

THE CHALLENGE OF PROVIDING DENTAL SERVICES TO INDIVIDUALS WITH DISABILITIES

Children with developmental disabilities are considered to be at a greater risk of developing oral disease and are more likely to have unmet dental needs than typically developing children (Norwood & Slayton, 2013). Not having a medical home is the strongest predictor of having unmet dental needs (McKinney et al., 2014), and individuals with developmental disabilities compared with individuals without developmental disabilities are less likely to have had a preventive dental visit and more likely to receive a lower quality of dental care (Kancherla, Van Naarden, & Yeargin-Allsopp, 2013). In addition, compared with the general population, those with IDD are more likely to have poorer oral hygiene, increased decay, and increased periodontal disease (Binkley et al., 2014). The reasons for this increased risk include 1) cariogenic diets and a preference for carbohydrate-rich foods, 2) medications that are high in sugar (Craig, 2017) or have detrimental side effects such as xerostomia or gingival overgrowth, 3) the inability to clear foods from the oral cavity, 4) physical or cognitive limitations preventing proper oral hygiene, and 5) dependence on a caregiver for oral health care. An inadvertent additional contributing factor to dental disease may be policies promoting community-based living arrangements that increase independence of people with developmental disabilities but decrease direct caregiver support (Norwood & Slayton, 2013). Finally, children with disabilities are now much more likely to survive into adulthood, thus increasing the long-term risk of dental problems (Norwood & Slayton, 2013).

According to a 2012 study, a majority of individuals with developmental disabilities have a usual source of medical care (93%); however, fewer reported having a dentist, and almost two thirds (62%) reported no dental care in the previous year (Morgan et al., 2012). A report from the National Study of Children with Special Health Care Needs (Maternal and Child Health Bureau, 2013) highlighted the finding that dental care was one of the services commonly reported as needed but not received. In addition, despite the trend of the improving condition of children's teeth noted in the 2016 National Survey of Children's Health (Centers for Disease Control and Prevention, 2017), children with developmental disabilities still experience barriers to accessing oral health care. A survey of families of children with special health care needs reported that in the 12 months before the survey, 24% of children needed dental care other than preventive services and 9% were unable to obtain the needed care (Norwood & Slayton, 2013). The families of children with special health care needs also experience higher expenditures for health care when compared with families without special needs children (American Academy of Pediatric Dentistry, 2017–2018b). It should also be noted that the out-of-pocket expenses of dental services are far higher than the costs of other health services for individuals with (and without) special health care needs. For families with limited financial means, this may result in their seeking less dental care. A common cited barrier to oral health care is financing and reimbursement (American Academy of Pediatric Dentistry, 2017–2018a). For many families of children with developmental disabilities, a lack of or inadequate dental insurance is a challenge (Norwood & Slayton, 2013). Many individuals with developmental disabilities utilize federal and state insurance programs to pay for dental and medical services (American Academy of Pediatric Dentistry, 2017–2018d; Centers for Medicare and Medicaid Services, 2014). Even those individuals with private insurance may lack or have restrictions on coverage, especially as they reach adulthood (American Academy of Pediatric Dentistry, 2017–2018b). As reimbursement rates for Medicaid are often below the usual and customary fees, many dentists, including pediatric dentists, do not participate in Medicaid insurance (Norwood & Slayton, 2013), further reducing access to care. It should be noted, however, that medical providers in many states are reimbursed by Medicaid programs for preventive dental care, including fluoride varnish application, so this should be pursued (Norwood & Slayton, 2013). Nonfinancial barriers that inhibit access to oral health care include transportation issues, physical barriers to and within a dentist's office,

family time missed from school and work, and difficulty locating providers who participate in the child's insurance plan, mainly Medicaid (American Academy of Pediatric Dentistry, 2017–2018b). Access to care also may be reduced by 1) referring a child too frequently to a dental specialist when an issue could be addressed by the primary provider, 2) not referring when appropriate, and 3) finding a qualified and accepting specialist (Morgan et al., 2012). Overcoming language barriers and developing effective communication are essential for understanding the child and family needs and desires as well as conveying the dentist's attitudes, capabilities, and plans. Additional challenges to access to care are psychosocial factors and cultural beliefs, including oral health beliefs, understanding of caregiver responsibilities, and past dental experiences of the caregiver (American Academy of Pediatric Dentistry, 2017–2018b). Another issue is the competency of the dental office to provide the services required. In the past, dental students received little to no educational experiences in caring for children and adults with disabilities, and despite a 2006 Commission on Dental Accreditation standard that requires dental schools to ensure that their graduates are competent in treating people with special needs, a 2012 study found that students are still inadequately prepared to meet the ongoing treatment needs of individuals with IDD. Complex medical conditions, the need for advanced management techniques such as sedation and general anesthesia, and a lack of facilities equipped to manage these procedures and trained personnel are challenges contributing to the access to care concerns. Pediatric

dentists are trained to provide treatment for patients with developmental disabilities; however, there are approximately 5,000 practicing pediatric dentists in the United States as compared with 60,000 general pediatricians. This number of pediatric dentists is too low to meet the treatment needs of this population (Norwood & Slayton, 2013). Oral health education in medical and residency training is very limited. A survey of pediatricians reported that only 36% of practitioners indicated that they had received training in oral health (Norwood & Slayton, 2013). Specialized oral health training is necessary for dental and medical providers in addition to auxiliary personnel in order to be able to address the oral health needs of children with IDD. In addition, the patient-centered care concept of integration of oral health into primary care is thought to increase the effectiveness of care for patients with special health care needs.

Providing patient- and family-centered oral health care for children with disabilities requires an understanding of the disability and associated medical conditions, along with behavioral, social, cultural and financial factors. These concerns may contribute to modifications of a traditional treatment approach (see Box 35.1). There may be commonalities associated with a specific type of disability, but each child's situation is unique, mandating pretreatment planning and proper assessment in order to accommodate the child with special health care needs irrespective of the type of disability (Moore, 2016). A comprehensive assessment of the conditions and circumstances allows for the personalization of the oral health care services for the

BOX 35.1 EVIDENCE-BASED PRACTICE

Silver Diamine Fluoride

Silver diamine fluoride (SDF) application has reemerged as a useful option in caries management for patients with special health care needs. SDF is available in the United States in a 38% formula. It can be utilized to arrest and manage caries in teeth in addition to other measures as part of a caries management plan within a dental home. Due the difficulties and limitations of safely and effectively treating the pediatric population with special health care needs, restorative treatment of dental caries often requires sedation or general anesthesia. SDF can be utilized chairside in uncooperative patients who cannot undergo traditional dental restorations, thereby avoiding sedation or general anesthesia.

SDF involves the application of a liquid to affected teeth, which results in the arrest of caries. Temporary fillings that release fluoride are often used along with SDF. Close monitoring and follow-up with the patient is necessary, as well as possible reapplications. Patient education and reduction of other caries risk factors are also important.

Systemic side effects of SDF application are minimal. The main disadvantage of SDF is the aesthetic result of dark discoloration of teeth after application; however, this is acceptable to many parents as an alternative to sedation or general anesthesia in order to complete restorative treatment (Crystal et al., 2017).

child. This requires intraprofessional and interprofessional collaboration and communication among a team of professionals with the goal of patient- and family-centered care.

As medical management may involve associated medical specialists in addition to a primary care physician, comprehensive dental management may involve a variety of providers as well. Oral health care providers may include a dental hygienist, orthodontist, endodontist, oral surgeon, periodontist, and prosthodontist. Interprofessional relationships are influenced by personal values, expectations, perceptions, and attitudes, as well as intraprofessional and interprofessional conflict, differences in terminology, complexity of care, fear of diluting professional identity, and varying levels of preparation (Quinonez, Kranz, Long, & Rozier, 2014; see Box 35.2). Physicians and dental health care providers may also report different barriers to the coordination of care (Quinonez et al., 2014). An oral health coordinator may assist by reducing the caregiver's barriers to care by providing education and assistance in locating and accessing oral health resources as well as assisting with scheduling and keeping appointments (Binkley, Garrett, & Johnson, 2010). Other professionals such as social workers and child life specialists may assist with reducing barriers and participating in care. Nutritionists are also contributing professionals, as children with special health care needs have risk factors and

comorbid conditions requiring nutritional interventions (Academy of Nutrition and Dietetics, 2015).

As children with disabilities present with a variety of dental, medical, and environmental issues, a collaborative team approach helps integrate oral health services into overall patient care. The Interprofessional Education Collaborative Expert Panel reported that professional teams working collaboratively communicate effectively, value each other's perspectives and contributions, understand and appreciate teamwork, and share an ethical code based on fair and high-quality care (Fried, 2013). This improved communication and coordination of care from intraprofessional and interprofessional collaborations suggest that an increase in the quality and safety of oral health care will follow.

Multidisciplinary risk assessment, oral health evaluation, preventive interventions, communication, and education are all considered necessary to provide and maintain access to a broad range of services for this population (Harnagea et al., 2017).

SUMMARY

- Oral health is an inseparable part of general health and well-being.
- Oral health care should include prevention and regular office visits through a dental home.

BOX 35.2 INTERDISCIPLINARY CARE

Oral Health Care Team Providers

Dental hygienist	Provides screening, teeth cleaning, examination, preventive oral health care, and patient education under supervision of a dentist or dental specialist
General dentist	Diagnoses and treats disease and pathology related to the teeth, gums, and oral cavity and provides oral health education and preventive oral health care
Pediatric dentist	Dental specialist that provides primary and comprehensive preventive and therapeutic oral health care for infants and children through adolescence, including those with special health care needs
Orthodontist	Dental specialist that provides diagnosis, prevention, and treatment of malocclusions and neuromuscular and skeletal irregularities of the orofacial region
Endodontist	Dental specialist that provides diagnosis, prevention, and treatment of diseases and pathology of the pulp and associated periradicular conditions
Oral and maxillofacial surgeon	Dental specialist that provides diagnosis and surgical treatment of diseases, injuries, and anomalies of the oral and maxillofacial region
Periodontist	Dental specialist that provides diagnosis, prevention, and treatment of diseases, injuries, and anomalies of the tissues surrounding and supporting the teeth, including the gingiva (gum tissue) and alveolar (tooth supporting) bone
Prosthodontist	Dental specialist that provides diagnosis and treatment of diseases, injuries, and anomalies associated with missing or deficient teeth and/or oral and maxillofacial tissues

CHAPTER 36

Assistive Technology

Larry W. Desch

Upon completion of this chapter, the reader will

- Know the definitions of the terms *assistive technology* and *medical assistive technology*
- Understand the types of conditions that frequently create a need for assistive technology
- Be aware of the major types of both habilitative/rehabilitative and medical assistive technology and know examples of each
- Be able to describe the key legislative and historical issues involving assistive technology
- Know the definition of durable medical equipment (DME) and the limitations that are often put on the purchase of DME by insurance companies and other third parties
- Understand the implications of assistive technology on the socioemotional functioning of children with disabilities and their families
- Understand the basics of proper assessment and training for users of assistive technology
- Know the essentials of funding for assistive technology and the laws dealing with this funding

More than a generation has passed since the technology that we now use on a daily basis, such as personal computers and cell phones, had its origins. Although much has been accomplished, for both able-bodied people and those with disabilities, several problems, such as equitable access and cost, still remain.

The goal of this chapter is to provide necessary information about the major categories of currently available habilitative/rehabilitative and medical

assistive technology and the process for evaluating their use and effectiveness. This chapter focuses on “mid-tech” and “high-tech” devices, as many “no-tech” (e.g., hands-on physical therapy) and “low-tech” (e.g., leg braces) devices and methods are discussed in other chapters of this book. Also, the chapter does not address complementary or alternative therapies (see Chapter 39), such as devices using unproven or disproven methodologies like colored lenses for the

treatment of dyslexia (American Academy of Pediatrics: Section on Ophthalmology et al., 2009). The devices discussed in this chapter have at least some basic empirical or scientific evidence to document their effectiveness.

Many children with disabilities are able to have more independent function through the use of assistive, adaptive, or augmentative devices. Although definitions for these types of devices vary, there seems to be some consensus emerging. Assistive devices are those that help alleviate the impact of a disability, thus reducing the functional limitations (e.g., tape-recorded lessons for students with a specific reading disability). Adaptive technology substitutes or makes up for the loss of function brought on by a disability (e.g., a sophisticated robotic feeding device provides independence for people with severe spastic quadriplegia). Augmentative devices increase an area of functioning that is deficient, sometimes severely, but for which there are some residual abilities (e.g., a microchip-powered voice output augmentative communication device for a person with severe dysarthria). The term **augmentative devices** currently refers mainly to devices used to improve communication. In this chapter, the term **assistive** is used to encompass all of these terms. This chapter uses this general term for medical devices as well. The term **medical assistive technology** refers

to that subset of assistive technology that is used for primarily medical or life-sustaining reasons (e.g., ventilators or feeding pumps). These devices also improve functioning but perhaps in more basic ways (often that are life sustaining).

For many years, assistive technology (sometimes called “AT”) has often been thought of as referring only to devices containing microcomputers or other electronics (Desch, 1986). Although such complicated devices may be the only answer for a particular disability-related problem, they represent the higher end of the spectrum of assistive technology that includes low-tech, mid-tech, and high-tech (and everything in between; Desch, 2008). Many people, even professionals working with children with disabilities, do not realize that they may themselves be using assistive technology on a daily basis. For example, a foam or rubber cushion placed over a pencil or pen to help with one’s grip and prevent writer’s cramp is a low-tech assistive device. However, the use of assistive technology is usually reserved for people with considerably more loss of function due to disability.

Table 36.1 provides examples of assistive devices. Many items on the table that are frequently used are no-tech (e.g., hands-on physical therapy) or low-tech assistive technology—that is, those using low-cost materials and not requiring batteries or other electric sources to

Table 36.1. Types of technology and examples of available devices

Area of disability	Low-tech	Mid-tech	High-tech
Physical	Swivel spoon (and other feeding aids) Wheelchair ramps Adapted playgrounds Most orthotics Grips for pencils	Reciprocating gait orthoses Lightweight wheelchairs Adapted toys	Electronically controlled wheelchairs Environmental control units Robotic therapy devices Functional electric stimulation Voice-input and eye-gaze-input devices
Communication	Simple picture/word boards Eye-gaze picture boards Visual schedule/planner	On/off light for yes/no responses One to multiple digital message recorders Scanning light board	Specialized software on iPad Dedicated speech-generating devices (e.g., Dynavox, Maestro)
Sensory	Magnifying lenses Large-print books Audiobooks	Alerting systems (to movement/sound) Braille typewriters FM transmitting	Digital hearing aids Cochlear implants Kurzweil 1000 voice-output scanning
Learning	Color-coded notebooks Post-it Notes Flash cards Visual schedule/planner	Talking calculators Electronic spelling/dictionary Tape recorders Audiobooks	Problem-solving software Hypertext learning programs Software for cognitive/attention rehabilitation
Medical assistance	Nasogastric tubes Bladder catheters	Oxygen systems Gastrostomy tubes Indwelling IV tubes	Home continuous positive airway pressure Home ventilators Oxygen monitors Apnea monitors Dialysis machines

operate. Examples include wheelchair ramps, gastrostomy feeding tubes, and printed picture communication boards. Mid-tech devices generally require battery/electrical power or are more complex in their use, such as teletypewriter devices for those who are deaf, home infusion pumps, suction machines, and sophisticated manual wheelchairs. Finally, high-tech devices are those that are complicated and often expensive to own and maintain. Examples include microcomputer-enabled voice output devices, home ventilators, cochlear implants, and electronic wheelchairs.

Assistive devices, across the spectrum, are acquired in one of three ways: 1) direct purchase from a commercial supplier; 2) development of a custom-made device (these can be simple, handmade devices or complex, one-of-a-kind devices made by an engineer or technician for use by one person); or 3) modification of an existing device such as a desktop computer, laptop computer, or telephone (these modifications can also be commercially available items). Some of these modified devices are constructed at rehabilitation centers at a high cost. However, the availability of microprocessing technology has increased such that the purchase of commercial devices or commercial modifications to devices is becoming the most common way to acquire even the most complex, high-tech assistive devices. Where assistive devices can be obtained also varies, from public schools and therapy providers to large university or private rehabilitation centers. Most assistive devices, excluding the medical assistive devices, can be obtained without prescriptions from physicians, although doing so usually precludes their purchase using insurance or other third-party, medical-related funding.

■ ■ ■ CASE STUDY

Laura is an 8-year-old girl who, according to her mother, “has come a long way” but had a “rough beginning” to her life. Laura and her twin were conceived by in vitro fertilization, were born 6 weeks’ premature, and had severe hyperbilirubinemia (jaundice) due to blood group incompatibility. She spent more than a month in the neonatal intensive care unit. Laura had occasional episodes of apnea and bradycardia (periodic breathing arrests accompanied by low heart rate) and was sent home on a cardiorespiratory monitor. At 6 months of age, she had severe **gastroesophageal reflux disease (GERD)**; stomach acid moves into the esophagus, causing discomfort) that led to placement of a gastrojejun tube. This required Laura’s parents to learn how to use a feeding pump that would give her formula over several hours. After 2 months, her feedings were able to be changed to oral, and by 1 year, she seemed to be doing fairly well

with feeding and in most other areas. At 16 months, however, she often would rock back and forth “for no reason” and was delayed in language. Soon thereafter, Laura was referred to early intervention, had an extensive evaluation by a team of developmental specialists, and was found to have an autism spectrum disorder (ASD). Despite intensive speech/language therapy for 9 months, Laura did not develop much speech and seemed to be getting increasingly frustrated because of her communication difficulties. Laura’s speech therapist recommended initially a simple picture-based card system and, later, a computerized speech-generating device. After nearly a year of negotiating with their insurance company and with Laura’s school, the parents were finally able to purchase the device. Laura gradually became less irritable and after 6 months of using the speech-generating device, she was beginning to say some words herself. By 6 years of age, she was talking in complete sentences and, as she no longer needed the device, it was donated to the local children’s hospital.

Thought Questions:

What are the factors that increase the chances that a particular technology will be used effectively? What are the emotional and financial stresses related to using assistive technology, including those from medical assistive technology?

TECHNOLOGY FOR MEDICAL ASSISTANCE

The Office of Technology Assessment defines a child who receives medical technology assistance as one “who requires a mechanical device and substantial daily skilled nursing care to avert death or further disability” (1987, p. 3). These medical devices replace or augment a vital body function and include respiratory technology assistance (e.g., nasal cannulae for oxygen supplementation, mechanical ventilators, positive airway pressure devices, and artificial airways such as tracheotomy tubes), surveillance devices (e.g., cardiorespiratory monitors and pulse oximeters), nutritive assistive devices (e.g., nasogastric or gastrostomy feeding tubes), equipment for intravenous (IV) therapy (e.g., parenteral nutrition and medication infusion), devices to augment or protect kidney function (e.g., dialysis and urethral catheterization), and ostomies (e.g., gastrostomy and colostomy).

The use of medical technology assistance by children is uncommon—occurring in only about 1 in 1,000 children—and most of these uses are temporary (e.g., following premature birth, injury, or surgery). In a survey of children in Massachusetts who were dependent

on technology, more than half (57%) had neurological involvement and 13% had multisystem involvement (Palfrey et al., 1994). The incidence does appear to be increasing, especially in children younger than 3 years of age, primarily as a result of improved survival of very low birth weight infants. Many of these survivors have a high risk for disabilities and chronic illnesses that need complex medical care (Elias & Murphy, 2012; Wise, 2007). More recent statistics on how many children are dependent on technology are difficult to obtain, but estimates in one U.S. state (Utah) has indicated that children on home ventilators represent about 1 in 10,000 children and that this number is likely increasing (Gowans, Keenan, & Bratton, 2007). The types of medical assistive devices that are required in a number of these chronic illnesses are described next, and the principles of device use with children are described in Table 36.2.

Respiratory Support

Infants and children who require respiratory support most often fall into one of two categories: 1) those with problems with their lungs and/or hearts and 2) those with problems with neurological control of breathing and/or weakness of the muscles used to control breathing. As an example of the first category, severe damage to the lungs related to prematurity, called bronchopulmonary dysplasia, can lead to the prolonged need for supplemental oxygen (Jobe & Steinhorn, 2017). Another example is the child with spastic quadriplegic cerebral palsy who may develop a severe scoliosis (curvature of the spine), leading to rib cage distortion and stiffness (see Chapter 21). This chest wall abnormality

can cause a decrease in respiratory muscle power and lung function necessitating supplemental oxygen. An example of the second category is neuromuscular disorders, including Duchenne muscular dystrophy (see Chapters 9 and 32) and spinal muscular atrophy (Farrar et al., 2017; Romitti et al., 2015; see Chapter 9).

Children who have chronic respiratory failure require medical technology assistance to maintain normal oxygen levels in the blood, prevent additional lung injury from recurrent infections, and promote optimal growth and development. These goals usually can be accomplished via a combination of oxygen supplementation, noninvasive ventilation using continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP), chest physiotherapy (CPT), suctioning, and medications (e.g., bronchodilators). When these treatments are ineffective or insufficient, however, mechanical ventilation and tracheostomy tube placement are considered. Equipment that is used to monitor the child's cardiorespiratory status may also be required (e.g., heart rate and blood oxygen monitors). Oxygen is often the single most effective agent in treating the infant or child with chronic lung disease, and supplemental oxygen may be required for months or even years. Oxygen can be administered by nasal cannulae (plastic prongs placed in the nose and connected to a tube that delivers an oxygen/air mixture), face mask, oxygen tent or hood, or an artificial airway (i.e., tracheostomy).

For the child with milder respiratory impairment or obstructive sleep apnea, nasal CPAP may be employed (Amin, Al-Saleh, & Narang, 2016). CPAP can be applied to the child's natural airway via a tight-fitting mask or nasal pillows/cannulae. For more

Table 36.2. Principles for assistive technology device use with children

1. Families are involved in selecting, developing, and implementing assistive technology (AT) devices for children.
2. AT devices should be an integral part of the child's daily routines across the home, child care, school, and other settings.
3. AT devices should be easy to use and adaptable to all of the environments of the child and family.
4. Families are always able to obtain needed AT from providers or a lending library and receive directions for using the device or an activity.
5. AT assessment and interventions should be done using an interdisciplinary team-based manner, with the family and child (if possible) being integral members of the decision-making team.
6. AT should be a consideration for every child during the development of the child's individualized family service plan (in early intervention) or with an individualized education program in school.
7. AT should always be seen as a tool to foster increased learning, functioning, and independence.
8. Providing appropriate AT should be done as early as possible in the child's life. Artificial constraints such as age should rarely be considered.
9. Families and professionals should have access to ongoing opportunities for training to increase knowledge and understanding of AT use and benefits.
10. Families and professionals should have adequate knowledge about funding sources for AT devices and for the training needed for these devices.

Source: Sadao and Robinson (2010).

severe conditions, CPAP is generally given chronically through a tracheostomy tube (Tibballs et al., 2010). If a child is on a mechanical ventilator, positive pressure can be administered between mechanical breaths, in which case the technique is referred to as positive end expiratory pressure (PEEP).

A recent advancement for children with chronic respiratory failure is the use of different types of noninvasive ventilation therapies (Bedi et al., 2018; Castro-Codesai et al., 2018). These often use a more sophisticated method of using CPAP or BiPAP, such as Auto-CPAP, which triggers the delivery of oxygen in response to taking a breath. The main difference between CPAP and BiPAP is that with CPAP a constant positive pressure is present and the patient is breathing spontaneously, whereas with BiPAP a ventilator supplies a pre-set positive pressure during inspiration and there is a lesser pressure delivered during expiration (PEEP). By using BiPAP, the lungs are kept open better, which helps improve gas exchange (e.g., O_2 and CO_2 ; Morley, 2016). For both CPAP and BiPAP, tight total face masks or tight nasal masks are usually needed because of the pressures that need to be present. The main purpose of using noninvasive ventilation (NIV) is to provide most of the benefits of invasive ventilation (e.g., oxygen through a tracheostomy) without the higher risk of infection and lung injury that can occur with these invasive measures.

Children with respiratory or oral-motor problems also may produce excessive secretions (e.g., saliva) and/or be unable to cough effectively. CPT and suctioning, which can be taught to all caregivers, help clear pulmonary secretions (Krause & Hoehn, 2000). CPT involves the repetitive manual percussion of the chest wall. For infants, this often involves using a handheld vibrator. Secretions are loosened and can then be cleared by coughing or, in children with tracheostomies, by suctioning. Typically, supplemental oxygen is administered before and after suctioning to prevent hypoxia from occurring during the procedure (Flenady & Gray, 2000). Suctioning and CPT are done as often as necessary, usually several times a day. The newest modalities for CPT are the use of automatic devices, such as the high-frequency chest compression vest or devices that cause vibrations of the lungs during breathing (Lee, Button, & Tannenbaum, 2017). A number of recent studies attest to these devices' effectiveness, especially in people who have cystic fibrosis (Dosman & Jones, 2005; Morrison & Milroy, 2017).

A tracheostomy involves the insertion of a plastic tube through a surgically created incision in the cartilage of the trachea, just below the Adam's apple. It is secured around the neck with foam-padded strings. This open airway can then be attached to a

mechanical ventilator or to a CPAP device with tubing that provides humidified air or an air/oxygen mixture. If ventilatory support or oxygen is not needed, then a humidifying device (an "artificial nose") is attached to the tracheostomy tube. A speaking valve (e.g., Passy-Muir valve) often is used with the tracheostomy tube to allow more air to go through the vocal cords to allow phonation (Buswell, Powell, & Powell, 2017). The tracheostomy tube also allows the caregiver to have direct access to the airway, permitting suctioning of secretions or removal of other blockages. Children who have tracheostomies may spend part or all of their day connected to a mechanical ventilator that augments or replaces their own respiratory efforts (Edwards et al., 2016; Edwards, O'Toole, & Wallis, 2004).

Monitoring and Surveillance Devices

Children with disorders that affect the heart or lungs are likely to require the use of monitoring or surveillance devices. Although these instruments provide no direct therapeutic benefit, they give early warning of problems and thereby improve care indirectly. The two most common types of electronic surveillance devices are pulse oximeters and cardiorespiratory monitors. They can be used individually or in combination in the hospital and at home.

To avoid giving too much or too little oxygen, **oxygen saturation** (the oxygen-carrying capacity of red blood cells) can be monitored using a device called a pulse oximeter. The pulse oximeter measures oxygen saturation in the arterial blood using a probe that is attached with special tape to one of the child's fingers or toes (Nadkarni, Shah, & Deshmukh, 2000). An alarm can be set to sound below a certain oxygen saturation level. This most commonly occurs when there is low oxygen delivery (e.g., kinked tubing or a low oxygen level in the oxygen tank) or a change in the child's condition (e.g., an increased need for supplemental oxygen because of a respiratory infection). Because this device reflects how well oxygen is being delivered to vital organs, it is an important monitor. Unfortunately, it is quite susceptible to false alarms resulting from probe displacement, movement of the extremity, or electrical interference.

A **cardiorespiratory monitor** has electrodes that are pasted to the child's chest to record heart and respiratory rate (Silvestri et al., 2005). An alarm is part of the system and is set off by rates that are either too high or too low. If the alarm sounds, the caregiver should examine the child's respiratory, cardiovascular, and neurological status. Like the oximeter, the cardiorespiratory monitor can produce false alarms, most commonly resulting from the inadvertent detachment of

the chest leads. In the very rare event that the alarm sounds because of a cardiorespiratory arrest (i.e., slowing or stopping of breathing and/or heart rate), cardiopulmonary resuscitation and possibly the use of an automated external defibrillator must be instituted immediately.

Nutritional (Gastrointestinal) Fluid Assistance

Children with cerebral palsy and other chronic neurological conditions are often limited in their ability to take in nutrition by mouth. Despite often needing an increased food intake as a result of their motor-control problems (e.g., dyskinesia), these children may be unable to ingest even a normal intake because of oral-motor impairments, GERD, or food refusal. In these instances, nutritional assistance devices may prove helpful. Tube feedings can be provided in a number of ways. The tube can be temporarily inserted into one nostril and passed into the stomach (**nasogastric tube**) or into the second part of the intestine (**nasojejunal tube**). When long-term feedings are required, a permanent tube can be placed directly through the skin and into the stomach (**gastrostomy tube**, or **G tube**) or intestine (**jejunostomy tube**, or **J tube**). A G-J tube combines a G tube and a J tube. The J-tube portion travels through the stomach, the duodenum (the first part of the intestine), and into the jejunum to prevent reflux of nutrients. If the child has GERD, the intervention of choice may be the combination of a surgical antireflux procedure (e.g., fundoplication by open or laparoscopic route; see Chapters 21 and 29) and insertion of a G tube or G-J tube. Once the feeding tube is inserted, nutrition can be provided by using a commercially available tube-feeding formula or foods from the family's meals that have been pureed along with fluids.

These types of tubes, especially G tubes, can be inserted using an endoscope and directly through the skin of the abdomen (percutaneous G tube) or by laparoscopic techniques or direct open surgical techniques. Recently, there have been reviews about which technique is the best surgical method of placing these tubes, especially G tubes. The growing consensus has been that, at the present, given no contraindications to a specific technique, the method that the surgeon is most comfortable with is the one that should be used (Baker, Beres, & Baird, 2015).

Intravenous Fluid Assistive Devices

Long-term IV therapy (months to years), generally given through a central venous line, is most often used

to provide nutrition and/or to administer medication (Hodgson et al., 2016; McNally, 2005). Total parenteral nutrition involves the provision of a high-calorie, high-protein solution directly into the bloodstream by IV administration. Prolonged IV access may also be needed to provide antibiotics (e.g., when a child has **osteomyelitis**, a deep bone infection) or for cancer chemotherapy. In these situations, a catheter (often called a central line, Hickman line, or Broviac line) may be tunneled into a deep vein under radiological guidance and advanced to a more central position near the heart. This type of catheter averts the need for repeated placement of regular IVs. In addition, a central venous catheter allows the child to receive medication and/or nutrition at home rather than having to remain in the hospital. Central lines are more stable than regular IVs and can be maintained for months or years provided that there is strict adherence to sterile techniques and proper care. For a need of a few week to months (e.g., for short-term parenteral nutrition), a peripherally inserted central catheter (PICC; Kovacich et al., 2016) can be used. For longer term but intermittent use (e.g., chemotherapy), a subcutaneous infusion port can be used (e.g., Mediport). Both of these can be very limiting to a child's movement, and the subcutaneous port needs to be prepared before use with a local anesthetic to lessen the pain of the needle insertion. However, the subcutaneous port greatly decreases the risk of site infections over that of a PICC line (Hodgson et al., 2016; Kovacich et al., 2016).

TECHNOLOGY FOR PHYSICAL DISABILITIES

Children with cerebral palsy or neuromuscular disorders commonly use assistive technology, especially low-tech devices such as ankle-foot orthoses, hand splints, and spinal braces (see Chapters 9, 21, and 32). Mid-tech devices include 1) functional electrical stimulators, which provide neural stimulation to increase mobility; 2) treadmills with support frames to increase strength even in nonambulatory people; and 3) dynamic braces for treatment of a hemiplegic arm. Personal computers, with the appropriate adaptations, can be very useful high-tech tools for people with physical disabilities. Transparent modifications to a computer can be made using add-on equipment and/or specialized software programs (Pousada, Pareira, Groba, Nieto, & Pazos, 2014). These modifications permit most commercially available software programs (including computer games, word-processing programs, and instructional programs) to be used. Transparent modifications do not modify or interfere with either the computer or the

standard software program. An example is the keyboard emulator, which is a device such as a joystick that replaces the keyboard (Keates & Robinson, 1999). Keyboard emulators are electronic circuits or switches that function by taking the output from a special keyboard or input device, altering it, and then translating the original signal into a different format that the computer interprets as coming from its own keyboard.

In addition to multiple-use devices, such as computers, many single-application devices have been designed or adapted for people with physical disabilities. Examples range from relatively simple mid-tech feeding devices to elaborate high-tech environmental control units that can turn lights and appliances on and off and can dial a telephone.

TECHNOLOGY FOR SENSORY IMPAIRMENTS

People with sensory impairments have been helped in many ways by assistive devices. For people with visual impairments, there are low-tech magnification devices; mid-tech aids such as alerting systems, laser canes, books on tape, or digital text-to-speech systems; and high-tech systems, such as personal computers with extra-large type on video screens. Various devices using electronic technology have also been developed for people who are blind. These include the Kurzweil 3000™ reading machines that translate printed words to voice-synthesized output and refreshable braille displays (e.g., ALVA BC680™) that provide an alternative access in the form of braille to the text or content displayed on a computer monitor or tablet (Thomas, Barker, Rubin, & Dahlmann-Noor, 2015; see Chapter 25 for more information on assistive technology for people with visual impairments). The near future also holds promise for those with visual impairments as devices using computerized camera systems (such as those in self-driving cars) are being researched with patients. These will serve as methods of augmented reality and will lead to independent accessibility in many places previously deemed too dangerous for someone who is blind or severely visually impaired (Coughlan & Miele, 2017).

Since the mid-1990s, there has been an explosion in the complexity and efficacy of hearing aids for people with hearing impairments. Digital programmable hearing aids have become more available, allowing improved customization for an individual's specific degree and range of hearing loss. Many mid-tech solutions are also available, such as assistive listening devices (infrared or FM transmitters) in movie theaters and classrooms and palm-sized telecommunication devices for use with telephones (Clark & Swanepoel,

2014). Especially for those children whose aided hearing ability is near to normal, there are now software programs available to further improve their speech and language abilities (Meinzen-Derr, Wiley, McAuley, Smith, & Grether, 2017).

For the child with a profound hearing impairment, as well as for their families and others, there have been advances in methods to learn lip reading and sign language by computer modeling programs. In addition, versions of the electronic cochlear implant (CI) have been gradually improving; for most individuals, this device can restore a type of hearing or at least an improved awareness of sounds (Marnane & Ching, 2015; Stern, Yueh, Lewis, Norton, & Sie, 2005). The surgical implantation of CI is not without risks, such as meningitis, and these children need careful follow-up (Rubin & Papsin, 2010; see Chapter 26 for more information on assistive technology for people with hearing impairments).

TECHNOLOGY FOR COMMUNICATION DISABILITIES

Many types of augmentative and alternative communication (AAC) devices exist to assist a person who is unable to use speech for communication (see Table 36.1). Most devices are used for people who have physical disabilities, but AAC has been shown to be quite effective for children who have ASD (Ganz, 2015, Schlosser & Wendt, 2008). Concerns have been raised in the past that using AAC might slow down the acquisition of verbal language, but research has shown that the use of AAC actually increases the development of speech (Binger, Berens, Kent-Walsh, & Taylor, 2008).

Low-tech devices include various lists of words or pictures mounted on durable material. These communication books or boards are used in face-to-face communication; the user points to the selected word or picture to communicate a specific message. A battery-operated scanning communication device using moving lights on pictures is an example of a mid-tech AAC device. Other mid-tech AAC devices include portable voice-output storage units that require direct selection and hold only a few minutes of prerecorded sentences or phrases.

High-tech electronic communication aids, often incorporating single symbols to substitute for groups of words, are becoming more commercially available. Various software companies have started using laptops or tablets as the core part of a communication system, increasing the versatility of these communication aids. Rather than being used only for person-to-person communication, these adapted portables can be used for

all types of communication, including letter writing, telecommunications, and e-mail. Adapted computers also can be the foundation for environmental controls, safety systems, and recreation (e.g., Internet access and virtual-reality computer games; Sigafoos et al., 2004; van den Heuvel, Lexis, Gelderblom, Jansens, & de Witte, 2016).

Despite what is portrayed on TV, when compared with high-tech computerized AAC technology, there are significant problems with low-tech and mid-tech devices: 1) they are slow in getting the message across, 2) they provide limited messages (i.e., usually only those about basic needs), and 3) they require face-to-face interaction. Spoken communication among typical individuals is normally performed at such a high speed that patience is needed for conversations between typically communicating people and those using a communication system (especially low-tech systems involving symbols, letters, or word boards). Although these methods are extremely slow, such boards should not be abandoned as they can often be very effective, especially for face-to-face communication. Further, electronic devices are sometimes limited by their need for a power source or the battery life, and most are not suitable for outdoor activities such as going to the beach or walking in the rain. Thus, low-tech solutions such as word and picture boards should always be part of an overall communication system and should be available as a backup to electronic devices, even if one has access to a spare battery or other power source.

TECHNOLOGY FOR COGNITIVE AND LEARNING DISABILITIES

Children who have learning differences have been helped by various assistive technology devices and strategies (Hettroni & Shrieber, 2004; Perelmutter, McGregor, & Gordon, 2017). Many software programs have been developed since the late 1980s that use computers to assist in reading, math, and other types of special education instruction. These programs range widely in price and utility, and only recently has

enough research been performed to begin to determine their effectiveness and generalizability, especially over the long term (Lahm, Bausch, Hasselbring, & Blackhurst, 2001; Liu, Wu, & Chen, 2013). Computer-based instruction, however, has several unique advantages, perhaps the most important of which is the ease of individualization. It is possible to build on children's strengths and talents and develop alternative ways of learning. Very few children in special education have their own personal teacher on a full-time basis; as such, the use of a computer can allow these children to begin to develop independent learning skills. It is crucial to first fully evaluate the educational strengths and needs of a student who has learning difficulties and then apply the assistive technology that can best help the problem. Most of the time, however, low-tech and mid-tech solutions should be considered initially. A high-tech solution is often not the best answer for a specific problem that a child is having in school.

ASSESSMENT FOR ASSISTIVE TECHNOLOGY

The assessment process and the prescribing of any assistive device must be done by a knowledgeable team of professionals. Depending on the type of assistive device to be prescribed, this interdisciplinary team may include a speech-language therapist, a physical therapist, an occupational therapist, a **rehabilitation engineer** (see Box 36.1), a neurodevelopmental pediatrician, a neurologist, a physiatrist or other physician, a special educator, a social worker, and a computer specialist. Also included in the team are the child who will be using the device(s) and his or her family members, who can offer advice that is critical in making final device recommendations. This team approach is essential to properly evaluating the child's motor and intellectual capabilities and narrowing down the devices that may fit within the child's abilities and needs (e.g., educational plans). Much of the research that has been done regarding the effectiveness of a team approach to assistive technology selection is based on adults

BOX 36.1 INTERDISCIPLINARY CARE

Rehabilitation Engineer

A rehabilitation engineer is a person who has college experience and training to be able to apply engineering principles and practices to the design, modification, and manufacturing of assistive technology devices. This individual's main function is to create practical, often individualized, devices in order to help people with various types of disabilities.

with disabilities (e.g., Scherer, Jutai, Fuhrer, Demers, & Deruyter, 2007). A clinical report from the American Academy of Pediatrics, however, is available that provides summarized information about this assessment process in children (Desch, Gaebler-Spira, & Council on Children with Disabilities, 2008).

Figure 36.1 summarizes the assessment process (also see the following section titled Functional Evaluation of the Individual for more information on the assessment tools mentioned in this figure). An important aspect of assessment is consideration of the range of assistive technology that may be useful. The best approach is to begin with the low-tech devices and to move on to mid-tech or high-tech devices only if needed. For example, to get around the home, a child with a severe physical disability may benefit more from ramps and wider doors than from a power wheelchair. The assessment process often involves making educated guesses (based on prior experiences with other people with similar disabilities) and then having the individual try out the chosen devices. A single-subject design methodology is often used to add some objectivity to this device selection process (Zhan & Ottenbacher, 2001). The most complete evaluation possible should be undertaken prior to purchasing the equipment, including testing the device in all settings where it will be used. This avoids buying a device that is unusable or inappropriate.

Figure 36.1. The assistive device assessment cycle. (Key: QUEST 2.0, Quebec User Evaluation of Satisfaction with Assistive Technology, Version 2.0 [Demers, Weiss-Lambrou, & Ska, 2000]; PIADS, Psychosocial Impact of Assistive Devices Scale [Day, Jutai, & Campbell, 2002; Routhier, Vincent, Morrisette, & Desauliers, 2001].)

Functional Evaluation of the Individual

The ultimate goal for a person using an assistive device is to achieve the highest possible level of functioning. The World Health Organization (2007) has introduced the International Classification of Functioning, Disability and Health-Children and Youth, a system that produces an overall picture of the capabilities of an individual, rather than solely focusing on the disability. A number of other standardized instruments have been developed that can be used to evaluate the current functioning and impact of treatment or intervention, including assistive technology, on children with various types of disabilities. These include the children's version of the Functional Independence Measure (Wong, Au-Yeung, & Law, 2005) and the Pediatric Disability Inventory (Ostensjo, Bjorbaekmo, Carlberg, & Vollestad, 2006).

Without the proper evaluation and ongoing support for the use of assistive devices, a number of studies have shown that there can be a significant amount of assistive devices that are abandoned shortly after they are obtained (Galvin & Scherer, 2004; Martin, Martin, Stumbo, & Morrill, 2011; Phillips & Zhao, 1993; Wessels, Dijcks, Soede, Gelderblom, & De Witte, 2003). To improve utilization, techniques have been developed to predict the successful use of assistive devices. One approach is the Matching Person and Technology (MPT) model (Scherer, 1998a, 2017; Scherer, et al., 2007) that stresses the importance of addressing environmental-, personal-, and technology-related issues. Environmental issues include the family structure and the work or school settings. The personal area includes recognition of functional limitations, motivation, coping skills, and personality traits (e.g., optimism). The technology area includes the characteristics of the assistive device, such as its reliability, ease of use, adaptability, and whether any discomfort or stress is caused by its use. Scherer and colleagues developed an assessment tool, the Assistive Technology Device Predisposition Assessment, which uses the MPT model to facilitate a match between the device and the person to ensure a good long-term result (Scherer, 1998a, 1998b; Scherer & Cushman, 2001). Table 36.3 lists factors that relate to this model. There are also assessment tools that determine the efficacy and satisfaction of the device once in place: the Quebec User Evaluation of Satisfaction with Assistive Technology (QUEST), now called QUEST 2.0 (Brandt, 2005; Demers, Weiss-Lambrou, & Ska, 2000; Demers, Weiss, & Ska, 2002), and the Psychosocial Impact of Assistive Devices Scale (PIADS; Day, Jutai, & Campbell, 2002; Jutai, Fuhrer, Demers, Scherer, & DeRuyter, 2006). Recently, a number of clinician/researchers have

Table 36.3. Factors associated with abandonment of an assistive device

Possible issues	Possible solutions/preventives
Improper or ineffective training on the use of a device (e.g., single-session training without follow-up and feedback)	Use a multidisciplinary or interdisciplinary team approach to training with the device.
Problems or obstacles in the environment preventing use of a device (e.g., second-floor rooms inaccessible to a power wheelchair user)	Assess <i>all</i> potential environments in which the device will be used.
Faults or failures in performance of the device (e.g., assistive device that is too sensitive to movement)	Consider using a rental or loaner device to try out. Become very knowledgeable about the devices being considered.
Device size, weight, or appearance (e.g., assistive device decorated with pink roses given to a boy)	Develop connections with several vendors of devices. Be creative with individualizing the devices (e.g., add colorful stickers).
Motivational factors in the user and/or family members (e.g., depression occurring after traumatic injuries)	Consider cultural factors. Social work or similar evaluations of the client and the family may be needed.
Perceived lack of or minimal need for the device (e.g., decision made not to leave the house rather than to use a wheelchair)	Consider cultural factors and socioeconomic factors (e.g., by social work assessment).
Functional abilities that worsen or improve (e.g., progressive disorder or recovery)	Ensure appropriate medical follow-up of the underlying condition (usually with subspecialists).

begun to systematically look at methods of assistive technology service delivery, especially to ensure that the person with disability is at the center of the selection process (Federici et al., 2014; Federici & Scherer, 2012; Box 36.2).

Training in the Use of an Assistive Device

Physicians, therapists, and educators who prescribe or recommend electronic assistive devices or assistive devices in general must ensure that the child receives proper training and monitoring for using the device. For some devices and software, demos and simulators are available (e.g., power wheelchair controls and AAC devices), which can help with training before the actual device is ordered (Faria, Reis, & Lau, 2014; Harrison, Derwent, Enticknap, Rose, & Attree, 2002). Simulators are especially helpful in evaluating reaction time, speed, and accuracy, such as in training with people with visual impairments (Todd, Mallya, Majeed, Rojas, & Naylor, 2015).

EFFECTS OF ASSISTIVE TECHNOLOGY ON THE FAMILY AND COMMUNITY

Assistive technology compensates for or builds on the individual skills that each person already possesses. It can lead to increased feelings of success and self-worth and, it is hoped, improved functioning (Guerette, Furumatsu, & Tefft, 2013; Wang & Barnard, 2004). For example, several studies have provided evidence for the positive effects of adapted toys on intellectual development (Logan et al., 2017). Although much uncertainty remains about the earliest age at which a child can successfully use an assistive device, some pilot studies suggest children even younger than 5 years of age can benefit. For example, studies demonstrated that children as young as 2 years old can be quite successful in using a power wheelchair and reap considerable social benefits from them (Guerette et al., 2013; Livingstone & Field, 2015). In fact, one study suggests that for children with communicative disabilities, if AAC devices

BOX 36.2 EVIDENCE-BASED PRACTICE

The Importance of Training and Follow-Up Tools

There is increasing evidence that using the assessment and follow-up tools described above in both adults and children with disabilities will lead to much better outcomes. Of course, when dealing with individuals who have varying disabilities, there can be instances of less than ideal results. Training in the use of devices by all involved is critical (see Desideri et al., 2016; Federici et al., 2015; Griffiths & Addison, 2017; Scherer, 2017).

are not being successfully used by first grade, the child will not be an active participant in the classroom setting (Buekelman & Mirenda, 2013).

Although assistive devices can markedly improve function, medical technology can also lead to social isolation. In school, the child is likely to be treated differently because of the accompanying equipment and medical/nursing needs. The presence of a tracheostomy and ventilator can be particularly intimidating. This can be partially offset by educating classmates and teachers and providing psychological counseling for the child. The child and family must also learn to deal with the underlying medical problem that led to the technology dependence. It is generally easier for a child and family to cope with medical technology assistance on a short-term basis, such as when IV antibiotics are necessary to treat a severe infection or when a temporary ostomy is required following abdominal surgery. If the child has a severe chronic disease, however, adaptation to assistive technology is only one issue that the child and family must face (Henderson, Skelton, & Rosenbaum, 2008). Studies have suggested that families fare better if the more significant type of technological assistance, such as mechanical ventilation, lasts less than 2 years. More prolonged periods are associated with an increased risk of parental stress and depression (Amin et al., 2014; Montagnino & Mauricio, 2004). The provision of in-home respite care and family-to-family support systems can be extremely helpful in these situations (Edwards, Morris, Nelson, Panitch, & Miller, 2017).

Despite financial and psychosocial difficulties, children who require chronic and substantial medical technology assistance are being included in their communities today (Feudtner et al., 2005; Seear, Kapur, Wensley, Morrisson, & Behroozi, 2016). A very useful, extensive, and practical book is available from the American Academy of Pediatrics that deals with home care (Libby & Imaizumi, 2009). Home care, especially when ventilator assistance is required, becomes a viable option only after a number of requirements have been met (Carnevale, Alexander, Davis, Rennick, & Troini, 2006; Heaton, Noyes, Sloper, & Shah, 2005):

1. The family must master the child's medical and nursing care.
2. The family needs to select a nursing agency if home nursing services are required and a DME supplier for equipment, disposable supplies, and in-home support (e.g., equipment maintenance and monitoring).
3. The funds to pay for all of these services also must be arranged.
4. Modifications to the family's home may be needed, such as changing existing electrical systems and adding ramps for wheelchair or adapted stroller accessibility.
5. If mechanical ventilation is required, local electric, ambulance, and telephone companies must be notified that a person dependent on life-support technology will be living in the family's home so that the household can be placed on a priority list in the event of a power failure or a medical emergency.

Medical, educational, and therapy (e.g., occupational therapy and physical therapy) services also need to be arranged before discharge from the hospital. A pediatrician or family physician in the community should be identified to provide a medical home. The discharging team should contact this physician prior to the child's hospital discharge to introduce the child and encourage the community physician's active participation in the child's care. If the child requires special rehabilitation therapies after discharge, either center- or home-based providers should be arranged. Educational services also need to be identified, and the child's health care and rehabilitative plans should be written into an individualized family service plan for early intervention services if the child is younger than age 3 or into an individualized education program if the child is preschool or school age (Lipkin, Okamoto, Council on Children with Disabilities, & Council on School Health, 2015). In addition, the school nurse needs to develop an individualized health care plan as well as emergency plans for the child. A center- or school-based educational program offers the child the opportunity to interact with other children in a stimulating environment (Behrmann & Schaff, 2001). These out-of-home experiences should be encouraged if the child's physical condition permits and if appropriate medical or nursing supports are available.

FUNDING ISSUES

Assistive technology can be very expensive depending on the type of equipment required, the extent of the disability, and the professional staffing needs of the child. For medical assistive technology, the two major issues are payment for home nursing care and DME and supplies (including technological assistance). It is sometimes easier to obtain funding for the former than for the latter; however, there is a national shortage of pediatric home care nurses. The primary source of funding for both is insurance, both private and public, and each has restrictions that may affect the provision of medical assistive technology. Every third-party

medical payment source has documents that detail which DME will be paid for and under what circumstances. It is crucial that both the providers (e.g., physician) and the family be familiar with this “approved DME listing” as it is difficult to get funding approval for items that are not part of the contract from the insurance carrier.

For assistive technology that can be used in schools, the Individuals with Disabilities Education Improvement Act of 2004 (PL 108-446) as well as other laws (e.g., the Technology-Related Assistance for Individuals with Disabilities Act of 1988 [PL 100-407], the “Tech Act,” and the Assistive Technology Act of 2004, PL 108-364 and various legal opinions about these), specifically indicate that funding should be provided for “technological” devices (including software) that are part of a student’s IEP. Yet, there are difficulties in actually finding funds to support this, and cooperative efforts among insurance companies, philanthropic agencies, school systems, and parents are often required. Another concern is that often schools will restrict the use of the software or device to the school program (and the student is not able to take it for use at home). However, if even 1 penny of Medicaid money is used by the school to purchase an assistive device for a student, then that student and family have the right to take the device home with them.

For some devices, such as home ventilators, suctioning, or specialized feeding equipment, insurance companies universally recognize that these are medically necessary DME and will pay for them. There continues to be controversy, however, as to whether other assistive devices are medically necessary or whether they are educationally necessary. For example, AAC devices, wheelchairs, or standing frames for children who have cerebral palsy could be used both at home and at school. If a device is shown to be primarily medically necessary, and therefore DME, it may be possible to obtain funding from medical insurance companies. If they are educationally necessary, the school system should purchase the needed devices. As mentioned before, The Tech Act has tried to solve this problem of discriminating between medical and educational use by legally allowing Medicaid funding to be used by the school to purchase the assistive device. The Tech Act further requires that the child be permitted to take home such devices for educationally related purposes. The Tech Act sets a precedent for all types of third-party medical funding to be at least considered for the purchase of essentially all assistive devices.

For years, most forms of private and government medical insurance (e.g., Medicaid) have been willing to

pay for the purchase of wheelchairs, and they gradually are beginning to fund other types of assistive devices. Fortunately, AAC devices are increasingly being seen as medically necessary in much the same way as wheelchairs. Physicians are often called upon to send medical necessity letters and prescriptions to funding sources for assistive technology (Cartwright & Council on Children with Disabilities, 2007; Desch et al., 2008; Lipkin et al., 2015; Sneed, May, & Stencel, 2004). This can best be done after the physician consults with the child’s therapists and then summarizes current abilities and expected outcomes from using the assistive device. Many assistive devices and their related professional services are relatively new and specialized, and they usually are not included on lists of approved products that are eligible for funding. As a result, many funding agencies need to be properly educated about the potential of these devices to improve functioning and independence for individuals with disabilities. Patience and perseverance are frequently necessary for funding to be secured. Initial denials of payment are almost automatic for some funding sources; however, these denials are usually subject to appeal and reversal. A clinical report from the American Academy of Pediatrics has additional information about the funding process, especially for AAC devices (Desch et al., 2008).

ADVOCACY INFORMATION

Fortunately, increasingly accessible sources of information about assistive technology have been developed. Statewide technological assistance services (“Tech Act sites”) are now available in all states, and information from them is becoming more widely accessible. ABLEDATA, which is funded by the National Institute for Disability and Rehabilitation Research, is an example of a large database that holds continuously updated information about assistive technology pertinent to many disabilities. In addition, various organizations dealing with children who have disabilities, such as the Council for Exceptional Children (<http://www.cec.sped.org>), have developed user-friendly online services that can be used to obtain references and abstracts about many facets of assistive technology, especially in regard to school-related services. On the Internet, there is an increasing number of sites offering resources for people interested in assistive technology, although many of these are thinly veiled advertisements from companies or sites that propose “alternative therapies.” Therefore, all web sites must be evaluated critically. Appendix D in the Online Companion Materials provides a list of reputable resources.

SUMMARY

- Most children with disabilities who use assistive technology employ it to make their day-to-day living easier or to improve functioning. However, some children use a medical assistive device that replaces or augments a vital bodily function, such as breathing.
- For the group using rehabilitative assistive technology (e.g., power wheelchairs, AAC, and hearing and vision aids), there is increasing evidence that it is best practice to provide access to appropriate assistive devices at an early age, thereby allowing the children to become proficient in use of the devices by the time they are young adults.
- Improved access to assistive devices also has social implications. As children with disabilities become better able to use their assistive devices or communication devices, they likely will be less isolated and have more contact with their communities as teenagers and adults.
- For children who require medical assistive technology (e.g., respiratory technology devices, surveillance devices, and nutritive assistive devices), the requirement for prolonged medical device assistance (and usually home nursing support) places many financial and emotional stresses on the family. It also leads to considerable challenges for health care professionals and other caregivers, especially in regard to the coordination of care.
- Training of caregivers and others in the use of life-supporting medical technology assistance is best done using a team-approach while the child is hospitalized. Arrangement for financial, nursing, and equipment support is essential before the child goes home.
- The outcome for any child who depends on any type of assistive technology appears to be more a function of the underlying disorder than the type or extent of technology. However, support for the family is essential.

CHAPTER 37

Family Assistance

Michaela L. Zajicek-Farber

Upon completion of this chapter, the reader will

- Understand the impact a developmental disability has on family functioning
- Be knowledgeable about strategies and resources that can help families cope with having a child with a developmental disability
- Learn the principles of family-centered care
- Recognize the influence of societal attitudes, provision of supports, and access to resources on the outcome of children with disabilities

The delivery of family-centered care through interdisciplinary care is essential for the well-being of families of children with disabilities, as a developmental disability has an impact on both the child's development and the functioning of their family throughout the life span (Carr & O'Reilly, 2016; Reichman, Corman, & Noonan, 2008). Families are not all alike, and whether a family has access to needed resources for meeting the needs of their child and how a family handles the day-to-day needs, wants, and stresses of its members influences the well-being, outcomes, and the quality of life of the child with disabilities and their family (Vohra, Madhavan, Sambamoorthi, & St. Peter, 2014). Professionals have come to realize that most families possess strengths and resiliency for guiding their own life course and for grappling with child-rearing issues regardless of the type and degree of their child's disability (Munford, 2016). In addition, more professionals have also come to appreciate the importance of listening to the immediate and long-term needs of the families (Zajicek-Farber, Lotrecchiano, Long, & Farber, 2015).

Building a collaborative partnership with families and other medical and nonmedical professionals in the community ensures the optimal care and quality of life for children with disabilities and their families. To be effective in promoting the well-being of families of children with various disabilities, professionals must apply family-centered care in service delivery (Seligman & Darling, 2007), strive to build quality medical homes (Zajicek-Farber, Long, Lotrecchiano, Farber, & Rodkey, 2017), and create effective transdisciplinary partnerships (Cumming & Wong, 2015). This chapter addresses issues that families face throughout their life cycle and the approaches professionals can take to help them.

■ ■ ■ CASE STUDY

Samantha is an 8-year-old girl with Down syndrome. When Samantha was born, her parents, Monica and Sean, were excited by the prospect of having their first child. Both parents were in their mid-to-late twenties, healthy, and well-connected with their extended families

and friends in the community. They were diligent about prenatal care, with Sean often attending prenatal visits with Monica. They were both employed full time, but Monica planned to take a 6-month maternity leave. Following a medically uneventful delivery, they were surprised and distressed to learn that Samantha had Down syndrome.

As a way to cope, Monica spent several hours in her hospital room refusing to see anyone, including Sean or her newborn. Sean left the hospital, trying to figure out what to do. He made calls to his and Monica's parents about the turn of events, and everyone in the family also became upset by the news. To provide quick assistance, the social worker coordinated an interdisciplinary meeting with their obstetrician and the lactation nurse. The obstetrician reviewed the health of their infant and noted that infant Samantha, although currently healthy, had a congenital heart defect that would need to be corrected surgically in the future. The social worker explained her role in supporting new families and provided a folder with a variety of resource information about maternal postpartum care, breastfeeding, infant care, and specific information about raising a child with Down syndrome. The nurse explained how she would provide support to Monica regarding Samantha's feeding. Monica cried as she breastfed Samantha for the first time. In the subsequent days, the social worker met with both parents several times, each time listening and supporting their emotional distress and helping them prioritize their decisions

regarding how best to meet with the rest of their family and explain Samantha's condition and needs. Eventually, the social worker and Samantha's pediatrician met together with the parents and one set of grandparents, while the out-of-town grandparents participated by a teleconference, to answer questions about Samantha's condition and care.

The whole family was overwhelmed. Monica and Sean kept asking, "What did we do wrong?" One set of grandparents worried whether they needed to do genetic testing on everyone in their family, and the other set worried whether Samantha would be able to attend regular school and support herself in the future. The social worker and the pediatrician answered many different questions about what the parents and extended family could do to help Samantha to develop in healthy and positive ways and how best to offer their support to Sean and Monica. This intensive meeting served as a precursor to many other meetings coordinated by the social worker.

Over time, the social worker provided direct care and counseling education and guidance with follow-ups, as well as emotional and mental health support and access to instrumental community resources. The social worker was key in providing family-centered case coordination with advocacy and ombudsmanship in collaboration with the pediatrician and other health care disciplines and community services (see Box 37.1). Through partnering with the family and providing ongoing social work and interdisciplinary support and resources, Samantha's

BOX 37.1 INTERDISCIPLINARY CARE

Key Social Work Roles and Services

- Family-centered assistance to help families gain knowledge of their child's condition, figure out the meaning of the symptoms that create a child's disability, and to cope with and adapt to changes of their child's disability and overall psychosocial functioning over time
- Direct and indirect care services to families to help them plan for their own and their children's developmental transitions over their life course
- Assessment of the psychosocial needs of the family and their child for ensuring and promoting healthy development and functioning
- Support with problem-solving by identifying and enhancing family and individual strengths and resiliencies and by removing barriers
- Education, counseling, anticipatory guidance, or therapeutic support services to families or their children to cope with distress and manage various life stressors in healthy ways
- Create access or build supportive resources for all individuals with disabilities in their community
- Collaborate and team with other health care and community providers to build and coordinate quality service delivery and ensure service follow-up
- Research and advocacy to ensure social justice and a healthy quality of life for children with disabilities and their families

parents learned about available supports for families of children with developmental disabilities, including those with Down syndrome.

The parents learned how to establish a medical home for Samantha (see the National Center for Medical Home Implementation: <https://medicalhomeinfo.aap.org/Pages/default.aspx>) that provided regular primary care and well-child follow-ups, and they also coordinated her ongoing medical needs with the hospital's Down syndrome community clinic and other medical specialists. They gained information on how to access early intervention (EI) services in their community for Samantha's early educational and developmental care (see ZERO TO THREE: <https://www.zerotothree.org/resources/83-making-hope-a-reality-early-intervention-for-infants-and-toddlers-with-disabilities>; Chapter 31), including nutrition and feeding, speech and language, and optimal ways for promoting parent-child attachment and bonding through play and regular parent-child interaction (see the Centers for Disease Control and Prevention: <https://www.cdc.gov/ncbddd/actearly/parents/states.html>). They learned about the individual family service plan (IFSP) and later about the individualized education program process used to guide formal education of children with disabilities under the Individuals with Disabilities Act (IDEA) of 2004 (see U.S. Department of Education: <https://sites.ed.gov/idea/>; Chapter 33). They received information on health insurance options and future life care planning for Samantha (see HealthCare.gov: <https://www.healthcare.gov/people-with-disabilities/coverage-options/>; U.S. Social Security Administration: <https://www.ssa.gov/pubs/EN-05-10026.pdf>; Chapter 41). They were provided with connections on how to meet other families of children with Down syndrome (see <http://Parent2Parent.org>) and with information on services that other families found helpful in caring for their child (see Family Voices: <https://www.familyvoices.org/>).

The parents learned how to gain emotional and mental health support for coping with the periodic distress often arising around Samantha's developmental transitions, as well as how to support each other as a couple and with their own individual needs. The social worker continued to meet with the family each time they came for Samantha's follow-up at the clinic, coordinated community services, and facilitated access to respite care. The family's social worker noted that over time, the parents' coping and adaptation changed in the context of Samantha's and family members' needs. Samantha's parents' feelings of distress, sorrow, and anger were periodically triggered by life-cycle events, such as when they first enrolled Samantha into a local preschool program that was unfamiliar with the needs of children with Down syndrome or when Sean became temporarily "downsized" in his employment and lost family health insurance. Such

feelings were balanced by her parents' ongoing love and commitment to Samantha's well-being and care.

With time, Monica became involved with the local Down syndrome organization and a resource to other parents; Sean became involved in the Special Olympics, assisting Samantha and other children with disabilities to participate in exercise, sports, and other socialization events. Their marriage went through stressful times, and following Samantha's heart repair, they sought marriage counseling that supported their bonds. Subsequently, they had two additional children; the youngest one has recently been identified with autism. Through their religious faith, one side of their extended family has adjusted to the unique needs of their grandchildren and maintains frequent contact; the other side, despite their faith adherence, continues to struggle. Today, Samantha's parents will readily tell you that having a child with disability is "just like having other children, but it's also different and unique." Consider looking at the Abilities web site for more information (www.abilities.com/community/parents-20things.html).

Thought Questions:

How can you work with families in a family-centered way? How does having a child with a developmental disability affect the various members of the family?

UNDERSTANDING FAMILY SYSTEMS

All families exist within the broader network of their communities and social environmental networks (Walsh, 2015). Bronfenbrenner's (1986) **ecological systems model** illustrates the interactive nature of family existence within a *microsystem*, *mesosystem*, *exosystem*, and *macrosystem* (see Figure 37.1). The family, through its matrix of activities, roles, interpersonal relationships, and material and physical characteristics, represents the primary microsystem. Each family interacts with other microsystems, such as child care, schools, employment, health care, and a variety of community programs. In turn, the interactions among microsystems constitute the mesosystem. The functioning of both the microsystems and mesosystem is further influenced by the exosystem and macrosystem. The exosystem represents the policy environment, and the macrosystem comprises the broader societal and cultural beliefs and values that influence all systems.

Within the microsystem, families are viewed as interactive, interdependent, or reactive, and when something happens to one member in the family, the whole family system is affected. Families differ with regard to their membership characteristics and views. Families

Figure 37.1. The living environment of children with disabilities and their families.

must be considered as configurations that include not only two-parent families, but also step-families, adoptive families, foster families, and intergenerational families. Families may consist of committed individuals who 1) may not be legally married, 2) have gay and lesbian partners, 3) are cohabiting or remarried heterosexual couples, 4) are widowed with children, or 5) are single parents. Families may be adversely affected by an unemployed “breadwinner,” a member with a major psychosocial disorder (e.g., substance abuse or mental illness), or a deceased family member whose cultural influence continues to permeate their thinking and behavior (Seligman & Darling, 2007).

A family system transmits traditions, values, ethnic heritage, and spiritual or religious beliefs. In turn, traditions provide members with guidance, strength, comfort, and strategies for coping with the difficulties of daily life (Mackelprang & Salsgiver, 2016). Beliefs,

communications, and interactions shape the family’s ideological style, relationships, and functional priorities. A family’s adherence to their ethnicity, culture, and religious/spiritual rituals; observances in public and private life; and socioeconomic and educational status all influence their cultural style and behavior, including their childrearing beliefs and parenting practices (Hanson & Lynch, 2013). Family beliefs can influence how much they will trust professionals, caregivers, or caregiving institutions and the manner in which the family adapts to their child’s disability.

As a family deals with their child’s disability, they also confront their beliefs systems about who and what can influence the future course of events (Farber & Maharaj, 2005). Some families believe that this control rests in their own hands (Siman-Tov & Kaniel, 2011), while others believe that control rests in the hands of their religious beliefs, fate, or even pure chance

(Goldstein & Ault, 2015). Family views influence the interpretation of events related to the disability, their help-seeking behavior as a response to the disability, and their approach to caregiving (Xu, 2007). Views and values also influence the family's ability to adapt, negotiate differences, manage stress, and make decisions. In turn, the family's adaptability influences their ability to provide many important supports to their child, including daily care, economic sustenance, housing, education, vocational skill development, socialization, community engagement, recreation, bonds of affection, and spirituality.

Moving through developmental life-cycle transitions can be a major source of stress and challenge for any family, particularly for those raising children with disabilities. Children with disabilities can both positively and negatively affect these and other family functions (Turnbull, Turnbull, Erwin, Soodak, & Shogren, 2015). These life-cycle events begin with the parent's marriage and move through childrearing, management of child schooling and adolescence, launching of young adults, postparenting, and aging. Stress in families is inevitable, but not all family members are impaired by it, and some stress fosters resilience (Valicenti-McDermott et al., 2015). However, accumulated stresses from unmet needs, lack of access to resources, and inadequate management strategies can impair adaptation and result in a crisis in the family's functioning (Neece & Chan, 2017). Fostering family resilience and adaptation is one of the major aims in providing support to families of children with disabilities (Benzies & Mychasiuk, 2009; Pickard & Ingersoll, 2017).

HOW FAMILIES COPE WITH THE DIAGNOSIS

When families are informed of their child's disability, individual members and families as a whole differ widely in their initial responses (Woodman & Hauser-Cram, 2013). Their reaction may depend on 1) the severity of their child's disability, 2) their preparedness for the possibility of this occurring, 3) their prior knowledge about the disability including their own beliefs about why their child might be afflicted with a disability, 4) their experience of interacting with an individual with a similar disability, and 5) the health care professional's manner of delivery of the news (Skotko, Capone, & Kishnanim 2009). The timing, the words used, duration of verbal exchange, and the emotional support that professionals provide greatly influence the family's response to the news (Abbott, Bernard, & Forge, 2013). The impact on the family also depends on their previous life experiences, religious and cultural

backgrounds, and age of the child at diagnosis (Vasilopoulou & Nisbet, 2016; White, 2009). Other factors that may influence their reactions include family members' beliefs about individuals with disabilities; knowledge of health treatments; and receptiveness to accepting help from professionals, friends, and other family members (van der Veek, Kraaij, & Garnefski, 2009). In other families, individuals who have had previous experiences with a family member with a disability may be able to adjust more easily to the news, or they may become more distressed depending on that previous experience. Some parents, after years of searching (Watson, Hayes, & Radford-Paz, 2011), may be relieved to finally receive answers and help for their child, but they may also express delayed anger at those who previously reassured them that their child would "grow out of it" (Chiu et al., 2014).

Parental Responses to Diagnosis and Stresses

Responding to the news that a child has a disability is unique, very personal, and often embedded in distress (Alexander & Walendzik, 2016). The most common initial response of parents is some combination of shock, denial, disbelief, guilt, and a sense of loss (Feniger-Schaal & Oppenheim, 2013). Some parents deny their child's diagnosis and visit various professionals, hoping that the conventional wisdom to "get a second opinion" will yield a more optimistic diagnosis or prognosis (Carlsson, Miniscalco, Kadesjo, & Laasko, 2016). Based on the complexity of the child's condition, some parents experience several misdiagnoses before a correct one is given (Mitchell & Holdt, 2014). Families have additional challenges when a child who initially develops typically later acquires a disability. They often have a difficult time accepting that prior aspirations for their child (and potentially for their family) may need to be adjusted. See the textbox titled Common Parental Reactions to Receiving News of their Child's Disability for more on this topic.

When a child's condition is difficult to diagnose, or when professionals are ambiguous or struggle in communicating the diagnosis, parental anxiety rises (Seligman & Darling, 2007). Not having a concrete or well-understood diagnosis is considered very stressful (Madeo, O'Brien, Bernhardt, & Biesecker, 2012). Professionals need to deliver the diagnosis honestly, with compassion, carefully choosing their words, and responding to any questions that parents may have. Professionals also need to understand that the questions parents ask at this juncture are likely to predominantly reflect the answers they are prepared

for or emotionally able to hear (Seligman & Darling, 2007). Professionals involved in establishing the diagnosis should provide parents with a written summary that captures the main points to be understood and schedule a follow-up meeting for review of details and answering questions. See the textbox titled Tips for Communicating the Hard News for more on how to best share the diagnosis with families.

After being informed of a diagnosis, parents usually experience a compelling need for information (Gundersen, 2011). While learning to understand the implications of their child's disability, parents experience various intellectual stresses, as they may be required to integrate vast amounts of information about physiology, timing and type of treatments, rationale for treatment approaches, and potential adverse effects and their management (Myers, Mackintosh, & Goin-Kochel, 2009). Families are also often faced with managing instrumental stresses that relate to 1) financing their child's needs; 2) dealing with learning about and administering unfamiliar insurance health policies; and 3) managing the division of labor for providing care for a child with special needs, while still accomplishing household chores and attending to the other family members' needs (Zuckerman et al., 2014). Families strive to normalize their life despite the immediate demands posed by their child's disability, but they come from a wide range of circumstances that may impinge on the child's care. Some families are very knowledgeable about their choices and can financially afford to obtain multiple expert opinions and services. Other families do not have a good understanding of the health care and educational systems or the means to obtain private fee-for-service programs. These problems, often combined with poverty, can directly affect the well-being of both the child and family (Corcoran, Berry, & Hill, 2015).

Specialized medical/therapeutic services and equipment, adapted toys and clothing, and alterations to the household environment can pose substantial financial burdens, which are often overlooked until they urgently surface. Using a **family-centered care** approach in partnering with families involves educating them about their child's condition, making them aware of the resources and entitlements available and helping them examine different treatment choices. Families who are knowledgeable about available resources and assertive in advocating for their child are usually better able to meet their child's needs (Blacher, Knight, Kraemer, & Feinfeld, 2016).

Along with intellectual and instrumental stresses, families also struggle with emotional stresses. Uncertainty regarding the diagnosis and prognosis is a major factor contributing to an emotional response to

a disability. As the child grows, family responses are subject to periodic exacerbations tied to their child's transitions within their developmental life cycle and to unexpected events (e.g., surgeries or new-onset seizures) that may be tied to the child's condition and health care needs. An uncertainty or ambiguity about a child's diagnosis/prognosis can compromise a parent's sense of control and create distress (Coughlin & Sethares, 2017). Children's ongoing manifestation of severe behavior problems (e.g., hyperactivity, self-injury, or aggression) can challenge parents' coping and leave them exhausted from the need for heightened supervision and sleep deprivation; it can even place them at risk for posttraumatic stress disorder (Stewart, McGillivray, Forbes, & Austin, 2017). Parents of children with rare disorders may feel particularly isolated, as they will not have a community of families dealing with the same condition (Anderson, Elliott, & Zurynski, 2013; Rivard & Mastel-Smith, 2014). For many families and allied health care, educational, and counseling professionals, a useful resource is the magazine *Exceptional Parent* (www.eparent.com), which provides practical advice and up-to-date information on resources and various products useful for families of children and adults with disabilities and special health care needs.

Common Parental Reactions to Receiving News of Their Child's Disability

- Shock, denial, numbness, disbelief, sense of loss for a hoped-for child, and even grief similar to death
- Feelings of crisis, confusion, guilt, shame, and responsibility
- Decreased self-esteem, feelings of devastation, and depression
- Strong anger directed toward the medical staff and professionals involved with the child
- Marital and other family relationships become severely strained
- Family functioning and routines are disrupted and become chaotic

Tips for Communicating the Hard News

- **Prepare and set the stage for a successful conversation:** Arrange to meet in a private setting. Dedicate as much time as you need to have a full conversation with both parents and/or family members. Turn

off your cell phone or any pagers. Understand that emotions may be unpredictable. Be ready to listen and to offer emotional and concrete support.

- **Put yourself in the parent's shoes:** Begin by making positive comments about the child's strengths and by reinforcing the parent's skills, love, and dedication to the child. Say things in a kind way. Keep your tone and manner open and available. Be nonjudgmental.
- **Start with the observations, questions, or concerns of the child's parent:** Gently probe and sensitively ask questions that will allow a parent to share their own observations, questions, or concerns first. Then share your own observations in small chunks. Check individual parent's feelings and understanding. Avoid rushing things. Be respectful.
- **Focus on the child's milestones and the need to "rule out" anything serious about the child's condition:** Give the parent something positive to read: Use an example of a developmental checklist of hallmark milestones and any red flags. If you use a web site, make sure that you review the information that the parent will see and read before the meeting.
- **Refer parents and caregivers to other resources:** Give written information summary on the developmental disorder, highlighting the main points. Help parents see the developmental disorder described in writing, whether through literature or on the web. Explain acronyms and avoid medical or other professional technical jargon.
- **Emphasize the importance of early identification and intervention:** Tell the parent that EI is key to help the child and that getting additional assessments of the child's language, behavior, and social interactions with others are just as important as any assessments for medications or procedures. Write down the names and contact information of any services that you recommend, make sure that you know these services well, and help parents prepare for recommended service encounters.
- **Take the time to listen to the parent and observe the child before you do, or say, anything:** Listening is key to being able help parents channel their concerns into words and actions.
- **Set a time for follow-up:** Be confident that sharing your concerns is always the right thing to do, but it takes time to process and absorb any news.

Sources: Centers for Disease Control and Prevention (n.d.) and Informing Families Project (2018).

Parental Depression

It is not unusual that after the initial shock or denial subsides, some family members experience depression (Resch, Elliott, & Benz, 2012). Such an emotional state can result from distress combined with the physical strain (or sheer exhaustion) of following through on the many appointments, procedures, recommendations, and care requirements for children with disabilities (Vonneilich, Lüdecke, & Kofahl, 2016). Other factors contributing to depression may be parental or guardian disagreement over the meaning of the diagnosis/prognosis, assignment of blame, sorting through the choice of treatment options, and/or responsibility in caring for the child (Stewart et al., 2017).

Women may tend to be more at risk for depression (Bailey, Golden, Roberts, & Ford, 2007; Barker et al., 2011). Symptoms of clinical depression include extreme fatigue, restlessness or irritability, insomnia, changes in appetite, and/or loss of sex drive. Professionals should screen for depression in family caregivers and refer them for further evaluation and treatment as needed (Gallagher & Hannigan, 2014). Parents' depression may also be accompanied by anger, which may be directed at a person, an event, their sense of divine intervention, or life in general. If directed at a person, the anger may be focused on the doctor, other professionals, the other partner, other children in the family, or the child with the disability; it may also be self-directed (Heiman & Berger, 2008). Regardless of where the anger is directed, it is important to recognize that such expressions are part of a coping strategy. Anger may well be an appropriate expression of frustration when parents feel their opinions are not being heard or respected. However, it may be inappropriately directed at a "safe" target (e.g., the partner) rather than at the person for whom it is felt (i.e., the professional who communicated the diagnosis). To support the family in managing their coping, the professional can suggest several evidence-based psychotherapeutic approaches to assist the family. Such common evidence-based therapeutic supports include **cognitive-behavioral therapy (CBT;** Singer, Ethridge & Aldana, 2007), **mindfulness practice** (Dykens, Fisher, Taylor, Lambert, & Miodrag, 2014), and **interpersonal psychotherapy (IPT;** Law, 2011). **Family therapy** can also be effective (Carr, 2014), and **behavior family therapy** is considered particularly useful when children's behaviors overwhelm parenting practices (Harris & Bruey, 2015). **Parent-child interaction therapy (PCTI)** has been used with a variety of families of children with different kinds of disabilities (Crnic, Neece, McIntyre, Blacher, & Baker, 2017), including those with a child with a severe developmental delay (Lesack, Bears, Celano, & Sharp, 2014).

Other therapeutic services are also available when parents struggle with domestic violence, abuse, neglect, or addictions or live in very impoverished environments (Tellegen & Sanders, 2013).

Accessing support from the family and community environment is critical for family well-being (Tint & Weiss, 2016). Families who have strong interpersonal relationships are better able to meet the challenges they encounter. However, sometimes, family or friends may be unable or ill-equipped to provide the needed support. The extended family may not accept the diagnosis or may assign blame to one of the parents, most commonly to the one unrelated to them. Friends may feel uncomfortable in the presence of the child with a disability, and, as a result, they may avoid interactions with the family. Parents may also be embarrassed by their child's disability or unable to manage their child's disruptive or oppositional behaviors and thus rarely venture into the community. They may find it difficult emotionally to see their friends' typically developing children. All of these factors can lead to family social isolation, and, in turn, undermine family management of their parenting (Skotarczak & Lee, 2015).

Family Coping

With time, most parents are able to cope with their child's disability and recognize positive outcomes from the experience. Signs of positive parental adaptations to a child's diagnosis include the following:

- Acknowledgment of emotional struggles in learning the child's diagnosis or condition
- Recognition of and reflection on changes in reactions since learning of the diagnosis
- Halt in the preoccupation with searching for existential reasons for child's condition
- Acknowledgment of the need to move on and go on making the best of life
- Recognition of child's strengths and capabilities in addition to difficulties
- Accurate representation of the range of their child's abilities

In many families, the process of raising a child with a disability increases cohesion, hardiness, and compassion among family members (Beighton & Wills, 2017). For some, it even leads to a more meaningful life (McConnell, Savage, Sobsey, & Uditsky, 2015). With experience and support, parents also become experts in meeting their child's needs. They develop assertiveness in learning to advocate for and obtain what is needed

from professionals and agencies to support their child. Their resilience and increasing abilities not only protect but also benefit the child, who may ultimately advance more than what was originally predicted at the time of diagnosis.

For most families, the sadness lessens as they develop routines for care (see the textbox titled *Stabilizing Effects of Child and Family Routines*), gain access to EI and respite care services, and begin seeing progress in their child's development (Horsley & Oliver, 2015). Naturally occurring family and child routines and meaningful rituals are particularly key in providing stabilizing and predictable structures that guide child behavior and the emotional climate during child development—especially when family life becomes stressful or when children are going through difficult stages or experiences (Boyd, McCarthy, & Sethi, 2014). The need for enhanced support and/or therapy, however, may recur at various developmental stages. The use of **telehealth** (Hinton, Sheffield, Sanders, & Sofronoff, 2017) or electronic and video-based communication is rapidly expanding and can be effectively used to support communication with families (Oberleitner et al., 2011). **Parenting networks** in which parents educate and support one another are often very powerful and may be even more effective in some cases than professional support (Wynter, Hammarberg, Sartore, Cann, & Fisher, 2015).

Stabilizing Effects of Child and Family Routines

"Because our daughter's needs were high, it almost seemed like the family routines we had went out the window. Getting a diagnosis and referrals to services and professionals was a tremendous relief, but then we were so busy that we still lived pretty much in chaos. It's so much better now that we have a routine that we usually stick to. Even if we can't all the time, I feel much better knowing it's there and we can eventually get back to it."

LONG-TERM EFFECTS ON THE PARENTS

Research on support to families suggests that services benefit families when they are delivered in a family-centered manner and address parent-identified and -prioritized issues (King & Chiarello, 2014). Research on

family-centered, help-giving practices (Dunst, Trivette, & Hamby, 2007) shows that to promote positive family functioning, service efforts need to do the following:

- Focus on family-identified needs, goals, aspirations, and plans
- Identify and capitalize on family strengths for harnessing resources
- Strengthen existing social support networks and identify other potential sources
- Use helping behaviors that promote family competencies and strengths
- Use linguistically sensitive communication strategies to convey care and empathy
- Promote collaboration in examining different treatments and service options
- Be proactive in mobilizing resources and exploring options for treatments
- Respect family choices for making decisions
- Engage in follow-up

Conducting an assessment of family strengths and needs is important when trying to determine how much assistance might be provided (Munford, 2016). Different assessment instruments exist for this purpose, including the Family Functioning Style (FFS) scale (Trivette, Dunst, Deal, Hamer, & Propst, 1990), the Parents Need Survey (PNS; Seligman & Darling, 2007), the Family Empowerment Scale (FES; Singh et al., 1995; Vuorenmaa, Halme, Åstedt-Kurki, Kaunonen, & Perälä, 2014), the Family Needs Inventory (FNI; Alsem et al., 2014), the Measure of Processes of Care (MPOC; Cunningham & Rosenbaum, 2014), the Family Support Scale (FSS; Dunst, Jenkins, & Trivette, 1984; Hall & Graff, 2011), the Feetham Family Functioning Survey (FFFS; Roberts & Feetham, 1982), and the Family Quality of Life Scale (FQOL; Hoffman, Marquis, Poston, Summers, & Turnbull, 2006).

Considering the many stresses families experience in childrearing, research has found that having a strong marital relationship, competent parenting and problem-solving skills, financial stability, and supportive social networks leads to more positive outcomes (Marshak & Prezant, 2007; Wang & Singer, 2016). Although some parental relationships are strengthened by challenges in raising a child with a disability, others deteriorate, especially if the relationship was previously troubled (Tomeny, Baker, Barry, Eldred, & Rankin, 2016; Wieland & Baker, 2010). Fostering early assistance through community affiliations and providing effective behavioral interventions in the home can

effectively increase family functioning, particularly when families struggle with alcohol abuse or other addictions (Petrenko, 2015).

Parents of children with severe developmental disabilities, chronic behavior problems, and/or medical fragility (e.g., requiring technology assistance to live and function) are at the greatest risk for caregiver burnout and impaired functioning (Ello & Donovan, 2005). Although many families with severely impaired children do well, some have considerable difficulties finding and being included within their community system of care (Overmars-Marx, Thomése, Verdon-schot, & Meininger, 2014). As a result, they continue to experience chronic stress (Coughlin & Sethares, 2017), which can lead to depression, physical illness, or post-traumatic stress disorder. When feelings of sadness or grief become chronic and interfere with the parent's ability to function, psychological intervention is indicated (Gordon, 2009). Kazak and colleagues (2005) contend that professionals need to explore how the family has dealt with previous stressors and whether the family members emerged with a sense of competence or insecurity.

Reframing and normalizing are important intervention strategies in helping families cope, particularly those with children whose disability condition requires technological dependence and support (Toly, Musil, & Carl, 2012). **Normalizing** involves communicating that the emotions and struggles experienced are both normal and expected (Rehm & Bradley, 2005). This approach from a professional can help reduce family members' feelings of isolation and stigma (Werner & Shulman, 2015). **Reframing** means reinterpreting a behavior or its context by viewing it through a different lens and focusing on the adaptive and positive aspects rather than negative ones (Neff & Faso, 2015). Family-oriented approaches are particularly effective in altering the counterproductive belief that children with disabilities should be the sole focus of family concerns. When in need, the whole family should take part in the intervention and be supported rather than the child alone (Seligman & Darling, 2007; Wang & Singer, 2016).

There is substantial research regarding how families of children with disabilities encounter barriers to inclusion in their communities and human services, including special education services and health care (Odom, Buysse, & Soukakou, 2011; Wehmeyer, Brown, Percy, Shogren, & Fung, 2017). Such difficulties are often compounded by some families' lower socioeconomic and educational status. Further barriers are also posed by providers' lack of training in providing culturally sensitive services to individuals with developmental disabilities, lack of acceptance of Medicaid payments, and lack of family centeredness in health

care service delivery (Magaña, Parish, & Son, 2015; Zajicek-Farber et al., 2017). To ensure that the values, beliefs, and perspectives of families are considered when conducting assessments and in developing and implementing services, Klinger, Blanchett, and Harry (2007) recommend that professionals do the following:

- Become knowledgeable about the impact that race, class, culture, and language have on families' access to services
- Communicate with families and their children (with or without disabilities) in their preferred language using professionally trained interpreter services
- Communicate in a manner that uses common (culturally sensitive) lay words and avoids overreliance on professional jargon
- Recognize that families may have their own individualistic ways of handling things that do not fit one "particular" culture or style
- Use multiple sources for assessment for determining family needs
- Give time and voice to both parents and their children
- Make sure that any printed materials are in the families' preferred language
- Whenever possible, provide services to diverse families within the inclusive context of community services

EFFECTS ON SIBLINGS

The siblings of a child with a disability have unique needs and concerns that may vary with gender, age, birth order, and temperament (Stoneman, 2005), as well as genetic predisposition and family factors (Orsmond & Seltzer, 2009; Tudor, Rankin, & Lerner, 2017). A number of years ago Coleby (1995) found that older male siblings had an increased appreciation for children with disabilities, near-age siblings had less contact with peers, and younger siblings of children with disabilities showed increased anxiety. More recently, Cridland, Jones, Stoyles, Caputi, and Magee (2016) found that older female siblings showed increased behavior challenges, perhaps because of being overburdened with child care responsibilities. Sibling concerns also appeared to reflect such situational variables as whether their own needs were being met, how the parents were handling the diagnosis emotionally, what information the siblings were being told, and how much they understood. More recent studies have also found an increased risk

for behavior problems (Platt, Roper, Mandleco, & Freeborn, 2014) and social impairment in siblings (Schwichtenberg, Young, Sigman, Hutman, & Ozonoff, 2010), especially in the presence of demographic risks such as immigrant status and poverty (Macks & Reeve, 2007). Giallo, Gavidia-Payne, Minett, and Kapoor (2012) noted that approximately 30% of siblings of youth with various disabilities may present with emotional or behavioral adjustment problems, although other studies have reported siblings to be well-adjusted (Ward, Tanner, Mandleco, Dyches, & Freeborn, 2016).

It is important to remember that children in general have mixed feelings about their siblings regardless of whether they have a disability (Carrillo, 2012; Schuntermann, 2009). Children may be glad that they do not have a disability but feel simultaneously guilty about this feeling. They may worry that they will "catch" the disability or fantasize that they actually caused it by having bad thoughts about their sibling. Adolescents may question whether they will pass on a similar disability to their future children. Due to the extra care and time required by the child with a disability, the typically developing siblings may think that their parents love their brother or sister more than them. As a consequence, siblings may misbehave to get attention, or alternatively they may isolate themselves, worrying about taxing their overburdened parents (Hartling et al., 2014).

Giallo and Gavidia-Payne (2006) found that parent and family factors were stronger predictors of sibling adjustment difficulties than siblings' own experience with stress and coping. In particular, family socioeconomic status, management of stress, degree of family time and routines, problem-solving and communication, and family hardiness influenced siblings' difficulties. Hence, care must be taken to balance parenting efforts to ensure that both children with and without disabilities are adequately supported (Kramer, Hall, & Heller, 2013).

Despite these concerns, some evidence indicates that siblings of children with disabilities may demonstrate increased maturity, a sense of responsibility, a tolerance for being different, feelings of closeness to the family, and enhanced self-confidence and independence (Taeyoung & Horn, 2010; Walton & Ingersoll, 2015). Some also choose to enter helping professions or become involved in advocacy (Hodapp, Sanderson, Meskis, & Casale, 2017).

Siblings of children with disabilities fare best psychologically when their parents' relationship is stable and supportive, feelings are discussed openly, the disability is explained completely, and the siblings are not overburdened with child care responsibilities (Lobato & Kao, 2005). Parents must remember that children

observe them closely and take their lead. Parents' approach to ensuring that all family members' needs are being addressed sets the tone for the entire family.

Children should be informed at an early age about their sibling's disability to ensure that their knowledge is based on facts, not misconceptions. This education must be done in an age-appropriate fashion, with the siblings feeling free to ask questions at any time. By the time the typically developing siblings reach adolescence, parents need to be ready to share with them information about genetic counseling, estate planning, guardianship arrangements, wills, and so forth. It is helpful for siblings to know what resources and options exist. Some siblings may choose to have their sibling with a disability live with them as adults, while others may prefer seeking independent or assisted living arrangements or other choices once their own parents can no longer provide the needed care (McHale, Updegraff, & Feinberg, 2016).

EFFECTS ON THE EXTENDED FAMILY

Having grandchildren creates strong feelings of satisfaction, fulfillment of life's purpose, joy, and comfort, but learning that a grandchild has a disability can lead to mixed feelings (Kolomer, 2008). Just like parents, grandparents can harbor guilt, assign blame, or even reject the child (Lee & Gardner, 2010). In addition, the quality of the relationship grandparents have with their own children affects their acceptance of their grandchild's disability (Findler, 2016). Typically, when a grandchild is born with a disability, grandparents grieve for their own loss of a "normal grandchild" and for their child's loss. Some may experience denial more strongly than do the parents, and their reaction can interfere with the family's adaptation to the disability (Seligman & Darling, 2007). Counseling, support groups for grandparents, and/or information given via the parents can lead them to become more supportive of the family and better able to cope with a child's disability (Kresak, Gallagher, & Kelley, 2014).

Grandparents can also be a strong source of support to the family. They may provide respite care, help out with household chores, and provide financial assistance, yet their support may also come at a cost to their own well-being (Miller, Buys, & Woodbridge, 2012). Other extended family members and friends can also help or hinder the parents' ability to cope. Some may have their own concerns or beliefs that interfere with their ability to be supportive; others may not know what to say or how to be supportive. In these instances, professionals can suggest ways to discuss these issues with family or friends, or create access to

other supportive social networks (e.g., advocacy groups for their child's disorder; Vora, 2016).

EFFECTS ON THE CHILD WITH A DISABILITY

Preschool Age

In early childhood, the child with a disability may not recognize that he or she is different from other children. Parents, however, closely scrutinize their child's development (Ray, Pewitt-Kinder, & George, 2009). Educating children in their naturally inclusive environments (Sood, Szymanski, & Schranz, 2015) and encouraging various play interactions serve as early typical learning experiences of young children that are equally important for children with disabilities (Myck-Wayne, 2010). Children's interactions with family members and peers during play serves as a preparation for future school interactions, and how parents manage those interactions is critical (Diamond & Hong, 2010).

Parent education regarding the process and course of their child's early development and a referral to EI and special preschool services are very important at this stage (Noonan & McCormick, 2013). Equally important is obtaining help for parents' management of children's early challenging behaviors (Chai & Lieberman-Betz, 2016). Federal legislation plays a key role in providing services to young children with disabilities. Part C of IDEA addresses the specific needs of infants and toddlers with disabilities (birth–age 3) and their families, and Part B mandates services for children ages 3–5 (Guralnick & Bruder, 2016). Children with disabilities and their parents who participate in EI programs often benefit from accompanying services (Zajicek-Farber et al., 2011). The focus on providing EI leads to interactions between parents and (often) multiple professionals to set up an IFSP, setting the tone for addressing the child's disability in the home and the community (Gatmaitan & Brown, 2016). This process, however, can be overwhelming for parents, and it helps when they work closely with the designated service coordinator or social worker on the interdisciplinary team (Rosenkoetter, Hains, & Dogaru, 2007).

School Age

By school age, most children with disabilities are aware of their abilities and challenges and may need help in dealing with feelings of being different. Weight management (related to being underweight or overweight) in young children with disabilities can present additional challenges for their immediate social participation

and long-term health (Emerson & Robertson, 2010; McGillivray, McVilly, Skouteris, & Boganin, 2013), and evaluation of mood and affect in children with developmental disabilities has been a growing area of importance in assessing their well-being (Leffert, Siperstein, & Widaman, 2010). Full acceptance of the child's abilities must first come from the home. If the child is seen as being worthwhile and capable by parents and siblings, his or her self-image is usually positive. This acceptance includes participating in family activities ranging from family events and vacations to religious services; community recreational programs; and, if possible, sports or physical play. This acceptance requires that the child's abilities (or lack thereof) are discussed openly and the child is involved in these discussions in an age-appropriate fashion. Discussing and demonstrating how to handle different situations at home improves the child's ability to cope with social situations in the community. Seeking input and guidance from teachers or school staff who interact regularly with the child can help identify the child's strengths and weaknesses in social interactions (Webb, Greco, Sloper, & Beecham, 2008). In order for school and community inclusion to work well, however, teachers and school personnel and community-relevant individuals must be adequately informed and trained about the specific needs of the child (Ryan & Quinlan, 2018). Research has identified care coordination as a crucial aspect of well-being for children with disabilities and special health care needs and their families (Hillis, Brenner, Larkin, Cawley, & Connolly, 2016).

The child with disabilities gains self-confidence through participation in activities in which he or she can be successful and through interactional experiences with others in their environment (Hong, Kwon, & Jeon, 2014). The philosophy of inclusion is that children who have disabilities can participate in general activities provided that they have or receive appropriate adaptations or assistance. Yet, successful inclusions require not only the philosophical and moral acceptance of the need for societal provision of support to children with disabilities and their families, but also the actual facilitation of access and creation of services for such needed support (Cummings, Sills-Busio, Barker, & Dobbins, 2015). Such an inclusive approach, however, should not preclude participation in specific (targeted) programs, such as the Special Olympics or camp programs for children who have varied abilities or specialized needs (Aggerholm & Moltke Martiny, 2017; D'Eloia & Price, 2016).

Some children with disabilities need encouragement and assistance in building social skills and developing friendships during typical social activities

(Rogers, Hemmeter, & Wolery, 2010). Summer camps that welcome children with varied needs provide an avenue to develop important socialization skills and experience independence from parents (Henderson, Whitaker, Bialeschki, Scanlin, & Thurber, 2007). Such participation encourages maturation and skill development for the child with disabilities (Goodwin et al., 2011). Furthermore, by participating in an inclusive environment, children and staff without disabilities learn more about tolerance, acceptance, and what it means to have a disability. In turn, they become more knowledgeable and caring of people with differences and less prone to bias (Siperstein, Glick, & Parker, 2009).

Adolescence

Transitioning to adolescence is an important time for families of youth with disabilities that needs to be anticipated, planned for, and well supported (Burke, Patton, & Taylor, 2016). Adolescence is a challenging period for all children and their families because many biological and social changes are taking place, and it can be a particularly difficult time for adolescents with developmental disabilities and their parents (Mitchell & Hauser-Cram, 2010). For parents, adolescence signals their child's proximity to adulthood and adult responsibilities. It quite naturally elicits anxieties and fears about independence, self-sufficiency, and maturity, especially when the child has a disability (Boehm, Carter, & Taylor, 2015). For adolescents, this is a period of many discoveries about self and others, and many adolescents become preoccupied with comparing themselves to their peers (Kuo, Orsmond, Coster, & Cohn, 2014). This desire for fitting in and peer approval in areas of physical and intellectual development may need to be adjusted because of limitations posed by the disability. Negotiating these differences tends to be less of an issue if the adolescent with a disability has 1) at least one supportive peer friend (with or without a disability), 2) a peer group with diverse members, 3) parents who actively encourage the adolescent's participation and involvement in activities that promote independence, and/or 4) the capacity to adjust to being perceived as being "different" (Zajicek-Farber, 1998).

Research shows that adolescents with developmental disabilities compounded with impaired cognitive functioning, as well as those with an acquired disability (e.g., from a traumatic brain injury), are at an increased risk for experiencing mental health difficulties. These often present as mood upheavals, anxiety, oppositional defiant disorder, inattention, aggression, self-injury, and other behavioral difficulties that compromise the adolescents' functioning and social interactions with

others (Green, Berkovits, & Baker, 2015). Effective treatment solutions for addressing the mental and behavioral distress of adolescents with behavioral disabilities is an ongoing area of need. Currently, pharmacology is often considered as the primary means for addressing oppositional behaviors or aggression in adolescents with disabilities (Park et al., 2016). However, pharmacology treatment alone has not always been an effective solution for addressing behavioral distress or aggression of adolescents with disabilities. Willner (2015) has shown that, with the possible exception of risperidone, there is no reliable evidence that antidepressant, neuroleptic, or anticonvulsant drugs are effective treatments for aggression in people with intellectual disabilities.

Others point to the fact that we need more and better understanding of the concept and meaning of mental and behavioral health in adolescents with disabilities. For example, Bermejo, Mateos, and Sánchez-Mateos (2014) have noted that the way in which people with intellectual disability express basic affect to emotional stimuli is very similar to that of the general population in terms of *happy-sad* and *calm-nervous*. However, there are also some real differences in the affective dimensions that have to be considered in our understanding of the emotional life of people with intellectual disability. Bradley, Caldwell, and Korossy reinforced this point by indicating that:

when people with intellectual and developmental disabilities experience mental distress, or their behaviors appear unusual, attending carefully to their communication in whatever way this occurs is crucial, as their perspectives on what may be causing this distress (or unusual behaviors), may be different from what might be concluded based on traditional psychiatric diagnostic frameworks. (2015, pp. 94–95)

Singh and colleagues (2014) demonstrated that mindfulness-based positive behavior support training can, for example, assist parents to effectively manage the challenging behaviors of their adolescents with autism and increase their positive social interactions without raising parental stress levels. Moskowitz and colleagues (2017) have also shown that when a **cognitive behavioral therapy (CBT)** approach was augmented with **applied behavior analysis (ABA)** and **positive behavior interventions and supports (PBIS)** school-age children with autism and cognitive impairments were able to significantly decrease their level of anxiety and their associated negative behaviors toward self and others. Moskowitz and colleagues (2017) also note that recognizing anxiety in children with disabilities can help parents, teachers, clinicians, and researchers regard challenging behaviors as potential signs of

anxiety (i.e., escaping anxiety) rather than noncompliance, disobedience, or defiance (i.e., escaping demand). In this way, identifying anxiety can help prevent challenging behaviors before they occur by reducing anxiety or teaching the child to cope with anxiety.

In sum, active professional vigilance is needed to screen and assess both the mental health of adolescents with developmental disabilities (Emerson, Einfeld, & Stancliffe, 2010) and the ability of the parents or caregivers to cope and manage the given situation (Zajicek-Farber et al., 2015). Research shows that anxiety and other mental health issues have been generally under-recognized in this population (Christensen, Baker, & Blacher, 2013; Rodas, Zeedyk, & Baker, 2016). In addition, adolescents with disabilities are at high risk for being excluded from typical daily activities, which, in turn, influences their emotional well-being. Jin, Yun, and Agiovlasis (2018) found that children with disabilities enjoyed the same activities as their typically developing peers. Activities allowing children to experience enjoyment (perceived as “fun”) have the best chance of ensuring children’s engagement and participation. Parents’ ability to encourage and promote the child’s engagement in the activity by their attitude, emotional responses, and use of resources is crucial for the child’s successful participation, particularly in sports or recreational activities (Rimmer, Rowland, & Yamaki, 2007; Rimmer, 2017).

Adolescents with disabilities who remain more isolated and parent dependent tend to struggle reaching a more independent adulthood and have poorer outcomes (Anaby et al., 2014). In addition, youth with disabilities need to be included in mainstream health promotion activities, including socializations and sex education (Akre, Light, Sherman, Polvinen, & Rich, 2015; Maart & Jelsma, 2010) in a way and at a level at which they feel comfortable and can understand (van der Stege et al., 2014). Management of personal hygiene—and competent health and safety practices in supporting a healthy adolescent intimacy and privacy—requires not only a high quality individualized mentoring of an adolescent with frank and sensitive dialogue, but also an individualized training and education of school staff or any health care providers (Wilson & Frawley, 2016).

Parents (and caregiving staff) also need to be encouraged to give the adolescents with disabilities the necessary freedom to become progressively more independent and take reasonable risks (Munro, Garza, Hayes, & Watt, 2016). Such an approach is best accomplished when parents/caregivers and professionals partner early to promote independence in youth with disabilities (Pleet-Odle et al., 2016). To help parents plan

for their adolescents with disabilities' futures, professionals need to support families in the following ways:

- Approach transitions universally by focusing on similarities among transitions at various life stages
- Focus on family services and supports throughout the life span, not just during early childhood or adolescence
- Begin the parental dialogue on envisioning and transition planning early and repeat and review at each transition
- Interact with families respectfully according to their unique cultural-linguistic preferences
- Partner with families to explore role models for their adolescent with disabilities
- Include the adolescent with disabilities in the dialogue with their family as much as possible, but also provide individualized mentoring and training for the youth to promote his or her self-determination in making choices and practicing their social skills
- Explore/create opportunities and provide concrete information for parents to learn about transitioning services from school to adult support services, eligibility, and how to gain access in their community

Allow for time to listen to parental worries or anxieties about their adolescents' future, but continue encouraging and empowering parents to trust their instincts for building support networks and planning for their adolescent's future in all domains: academic, recreational, extracurricular, vocational, spiritual, social and community involvement, and health care.

Young Adulthood

The transition to adulthood is both important and difficult for adolescents with disabilities and their parents (Landmark, Ju, & Zhang, 2010). For these adolescents, leaving school creates many worries and anxiety beyond those of typical adolescents; however, with ongoing discussions regarding their concerns and with early anticipatory planning, they can be supported to transition into young adulthood according to their needs (Young, Dagnan, & Jahoda, 2016). Carter, Austin, and Trainor (2012) found that for adolescents with severe physical or intellectual disabilities, the factors that best predicted the future likelihood of securing a meaningful employment included having hands-on employment experiences (paid or unpaid) during high school years, being involved in more household responsibilities, and having parents with higher expectations for their adolescent's abilities. Ju, Zeng, and

Landmark (2017) examined the postsecondary school achievement of students with disabilities and found that self-advocacy, self-awareness, problem-solving, and goal setting/attainment are important individual traits of successful individuals with disabilities. They also noted that related trainings (e.g., self-advocacy training and coaching services) were found to improve social skills and encouraged students to utilize community available disability services and support systems to achieve academic success.

Objective role transitions, such as finishing school, finding full-time paid employment, getting married, and starting a family, have been the most common criteria used to evaluate success in adulthood for typically developing youth. However, these role transitions are also becoming less reliable indicators of adulthood, as changing societal economic (employment-related) and social (educational demands-related) conditions continue to alter the traditional paths to adulthood for all youth and especially those with disabilities (Settersten & Ray, 2010). Therefore, a young adult's ability to cope and become as independent as possible depends not only on the management of the disability, but also on 1) the effectiveness of the family to plan and manage this transition emotionally and financially (see Leonard et al., 2016, and Chapter 40) and 2) the community's willingness and the legal support to determine access to support services for children, adolescents, and adults across their life span (Rattaz, Michelon, Roeyers, & Baghdadli, 2017).

Although some adolescents with disabilities *do* achieve independence, many struggle, and some never attain this goal (Henninger & Taylor, 2013). For young adults who cannot achieve true independence, limited alternatives are available depending on where they live, their family finances, and their individual self-care abilities. Much also depends on the existence of societal supports that may or may not exist for supported employment and inclusion of adults with disabilities into normalized community living and activities (Henninger & Taylor, 2014). Research shows that the quality of life of families of young adults with disabilities improves when they are supported by societal resources that help them plan for long-term guardianship across the life span and adjust to the implications of having an adult child with disability (Lindsay & Hoffman, 2015; Stewart et al., 2014). Such services typically need to include the following:

- Identifying options for an appropriate and possible range of living environments for their young adult or child with disability
- Finding appropriate vocational and/or employment opportunities and services

- Planning for how the adult-age child may navigate transportation and mobility in the community and in personal living environments
- Addressing special or unique issues of socialization, intimacy, sexuality, and procreation
- Recognizing the need for socialization opportunities and community connectedness
- Facilitating transitioning to and coordinating adult health care services
- Managing the continued financial implications of lifelong dependency.

Professional Behavior Using Principles of Family-Centered Care

- Demonstrate respect and sensitivity for the child and family in all types of interactions, including verbal and nonverbal communication.
- Be knowledgeable about and recognize the importance of racial, ethnic, cultural, linguistic, and socioeconomic diversity and these factors' effect on the family's experiences in seeking help and their perception of care and support.
- Actively seek to identify the strengths of each child and family and help the child and family use these strengths to promote their natural resilience and address challenging situations.
- Facilitate a partnering climate and time and encourage the child, the adolescent, and the family to ask questions and express their choices about treatment, care, and support.
- Explore options and potential effects of different choices for treatment and care with both the child and family, encourage their input and feedback, and acknowledge their preferences and choices.
- Assist the family in obtaining interdisciplinary and transdisciplinary input and coordination of care regarding options for treatment and support services.
- Ask about barriers or challenges the child, the adolescent, and the family may be experiencing in their psychosocial adjustment to treatment, care, or receipt of support.
- Engage in anticipatory guidance and provide and share with the child and family the types of available formal and informal support services that might be helpful for ensuring healthy child and family functioning during critical and transitional developmental periods.
- Encourage the separate input and advocacy of the child, the adolescent, and the family in all forms of professional interaction, education, and the development of policies for treatment and program interventions.
- Ensure flexibility in developing organizational policies, procedures, and providers' practices so that all services can be individualized to the diverse needs, beliefs, and cultural values of each child and family.
- Strive to collaborate and partner with families at all levels of health care service delivery.

PRINCIPLES OF FAMILY-CENTERED CARE: ROLE OF THE PROFESSIONAL

The textbox titled Professional Behavior Using Principles of Family-Centered Care lists principles of family-centered care that represent the current philosophy guiding the interactions among professionals and the families of children with disabilities (Zajicek-Farber et al., 2015). The goal of family-centered care is to facilitate the best possible outcomes for both the children and their families. To achieve this goal, professionals must initiate a process of service delivery and support that invites and establishes a collaborative relationship based on mutual respect and open communication. When such a family-centered relationship is forged, families come to see the professionals as partners who are flexible in solving problems and in giving constructive feedback. Professionals are also then seen as being respectful of cultural diversity, sensitive to family's linguistic issues, and able to listen to family needs with empathy and compassion. Through this shared focus, both families and professionals can appreciate the unique expertise that each contributes (Zajicek-Farber et al., 2017).

Over time, families of children with disabilities may encounter a bevy of professionals including physicians, nurses, teachers, physical and occupational therapists, psychologists, social workers, and agency or hospital administrators. Individually, and

as a group, professionals bear the primary responsibility for explaining the results of developmental evaluations and testing, presenting treatment options, teaching intervention and advocacy strategies, and exploring and accessing available support systems. The initial contact that families have with professionals often takes place during a crisis when they are stressed, confused, and vulnerable, and how professionals respond to them sets the tone for future interactions (Vohra et al., 2014). Wright, Hiebert-Murphy, and Trute (2010) examined professional perceptions and organizational factors that support or hinder the implementation of family-centered practices. These included the organization's culture and climate (e.g., caseload size and activity, supervision, staff training), policy limitations, and availability of collateral services. Other research has found that when the case workers provided emotional support, information, and assistance in identifying and meeting family needs, along with advocacy and service coordination, outcomes for children with disabilities and their families improved (Wright, 2013).

As a result of their training, experience, and expertise, professionals often have strong opinions about what is best for the child and family. Yet, they must remember that individuals with disabilities and their families have the right to choose their own path. Families who make their own choices are better at attaining their goals and addressing their needs (Hiebert-Murphy, Trute, & Wright, 2011). However, when the choices the family makes are perceived as potentially deleterious to the child's well-being, the professional must take responsible and ethical action. For example, it is the professional's responsibility to inform the family of the risks and benefits of validated and nonvalidated therapies, while respecting the family's autonomy. The one exception is when it is believed that the family's actions may be harmful to the child or individual with disabilities. The professional must then contact the local child welfare agency (or protective services) to report the professional's suspicion or knowledge of abuse or neglect. Research unfortunately shows that children, adolescents, and adults with disabilities are more likely to be abused than their peers without disabilities (Byrne, 2017; Euser, Alink, Tharner, IJzendoorn, & Bakermans-Kranenburg, 2016; Rowsell, Clare, & Murphy, 2013; Stalker, Taylor, Fry, & Stewart, 2015).

THE ROLE OF SOCIETY AND COMMUNITY

The family's community and environmental context plays an important role in determining the social inclusion and outcome of its members (Simplican, Leader, Kosciulek, & Leahy, 2015). In today's society, there is

a greater acceptance of people with disabilities being members of the community, and there are more educational, vocational, housing, and support services available, including religious participation (Ault, Collins, & Carter, 2013). Federal legislation guarantees equal opportunities for all members of society. Federal funding provides for a protection and advocacy system for people with disabilities in each state. IDEA (2004; PL 108446) mandates free and appropriate educational and rehabilitative services for school-age children. Reaching citizens of all ages with disabilities, the Americans with Disabilities Act (ADA) of 1990 (PL 101-336) focuses on the establishment of rights regarding access to employment, transportation, telecommunications, and public accommodations. Effects of the ADA are visible through the presence of accessible city sidewalks, ramps on buildings, public transportation equipped with wheelchair lifts, accessible computers in libraries, and other technological advances. As a result of these efforts and other laws (e.g., the Assistive Technology Act of 2004), individuals with disabilities and their families are guaranteed the same civil rights as individuals without disabilities (Bausch, Ault, & Hasselbring, 2015). However, advances in technology can have both positive and not-so-positive effects (Ellis & Goggin, 2015). For example, while technological advances have improved the communication options for people with disabilities, such as through social media (Gips, Zhang, & Anderson, 2015), cyberbullying of children, adolescents, and adults with cognitive impairments has become a rising societal concern (Carrington et al., 2017; Hernandez, Brodwin, & Siu, 2017).

Although laws are important, they need to be accompanied by a change in the public's perception and attitudes toward individuals with disabilities (Mackelprang & Salsgiver, 2016). Reducing societal stigma toward disabilities (Lalvani, 2015), increasing social inclusion (Anastasiou & Kauffman, 2013), and ensuring equitable supports for aging parents providing lifelong care for their adult children with developmental disabilities should be ongoing goals for our society (Seltzer, Floyd, Song, Greenberg, & Hong, 2011).

Signs of improvement in societal attitudes, in fact, seem to be emerging. Young adults who have grown up in schools with children with disabilities are more sensitive to and appreciative of their needs and abilities. More individuals with disabilities are now in the workforce. Individuals with disabilities are often portrayed in a positive light in movies, television shows, advertisements, and the news. Adaptive and assistive technologies, including the use of universal design, are slowly removing barriers and increasing overall societal integration of individuals with diverse abilities (Burgstahler, 2015). However, although society has

made itself more accessible to and supportive of individuals with disabilities, the future remains challenging and requires ongoing vigilance and advancement (Bumble, Carter, McMillan, & Manikas, 2017).

SUMMARY

- A child's developmental disability impacts the life course of his or her development and also all members in the family.
- Initially, the family goes through periods of grieving and disappointments for the loss of their imagined "typical life" for their child.
- Over time and with support, the family's coping strategies evolve and generally improve.
- Parents learn to master their child's care and become more effective supporters and advocates for their child's health, education, and other needed services.
- Over time, youths with disabilities gain skills to cope and manage their own disability and learn to become self-advocates.
- Each developmental transition brings about challenges and changes that impinge on the adapting and coping of the child with disability and his or her family.
- Working in partnership with the parents and the child with disability, the social worker, along with the medical and nonmedical providers in the community, provides an important role in promoting and supporting the health and psychosocial well-being outcomes of children with disabilities and their families.

CHAPTER 38

Pharmacological Therapy

Shogo John Miyagi and Johannes N. van den Anker

Upon completion of this chapter, the reader will

- Understand the role of medication in the treatment of children with disabilities
- Be able to describe the factors for consideration when starting medication in children with disabilities
- Advocate for the safe and effective use of medications in children with disabilities
- Appreciate the issues surrounding the use of complementary and alternative medicine

Pharmacotherapy plays an important and vital role in the treatment of children with developmental disabilities. Medications will not cure a child, but they can help to alleviate symptoms associated with the child's condition. Such medications include anti-epileptic drugs for seizures, stimulant medication for attention-deficit/hyperactivity disorder (ADHD), spasticity medication for cerebral palsy, and enzyme replacement therapy for inborn errors of metabolism. There may be multiple medication options for each condition or symptom, but each drug also has associated adverse effects. Some may be serious, such as hepatic failure, whereas others may be less severe, such as drowsiness. In addition, children metabolize and dispose of drugs differently than adults based on their developmental stage. The pediatric population ranges from premature neonates through adolescents and can vary in weight between 0.5 kg to over 100 kg (de Wildt, Tibboel, & Leeder, 2014). Further complicating the use of medication in children

is the relative lack of clinical trial studies of drug efficacy, side effects, and proper dosage in children of different ages and medical complexities (Frattarelli et al., 2014). Yet, it is important to be able to balance the risks and benefits associated with each medication prior to starting pharmacotherapy (Elzagallaai, Greff, & Rieder, 2017). This chapter will highlight important factors to consider when initiating drug therapy in children with disabilities. In addition, the chapter will cover techniques and methods to help parents and families ensure optimal drug therapy for their children.

■ ■ ■ CASE STUDY

Zachary is a 5-year-old boy who is in kindergarten. His mother expresses concern during their annual well-child visit that he has been disruptive in class and is having difficulty paying attention and following directions. She also notes that he started behaving this way during

preschool but that she had attributed this to her son being immature. After further evaluation by the physician, it was concluded that Zachary may have ADHD, the inattention subtype. Upon hearing the diagnosis, the mother asks if methylphenidate would help her son because it has “cured” her friend’s 14-year-old daughter who had ADHD. The clinician explains to the mother that behavioral therapy is the first-line treatment and most effective in this age group. The mother pushes the clinician, saying that she is a single mother with two other children and it may be difficult to also include behavioral therapy into her busy family schedule; she asks again for a medication option. The clinician stresses that behavioral therapy is the best treatment option for Zachary and that they can reassess his progress in a few months. The mother agrees to the plan and is connected with a behavioral therapist and a school counselor to develop a behavioral management plan for Zachary as part of a 504 program.

■ ■ ■ CASE STUDY

Isaac is a 6-month-old boy who was born with cerebral palsy resulting from severe hypoxic-ischemic encephalopathy (HIE; see Chapter 21). On his recent clinic visit, his mother mentioned that Isaac seems to make a fist almost constantly and that it is difficult to unbend his knees and arms when changing his clothes or diaper. Upon further examination, Isaac showed signs of spasticity. To help alleviate this symptom, the physician prescribed baclofen 0.2 mg per kg, three times per day orally (the body weight is 5.5 kg for a total dose of 1.1 mg per dose) and asked the mother to return to the clinic within 2 weeks to see if the baclofen had any beneficial effect. Upon returning, the mother stated that baclofen was showing no effect, positive or negative. The physician gradually increased the dose until Isaac’s hypertonicity improved; the final dose was 6 mg (1.1 mg per kg per dose) given three times per day. At the next clinic visit, the mother expressed concern that he was getting too much baclofen because the dose was twice what she had found on the Internet to be typical. The physician reassured her that this dose was acceptable for Isaac as long as he was not experiencing any undesired side effects (e.g., drowsiness). Isaac’s mother confirmed he had not had any side effects and therefore she continued Isaac on the prescribed baclofen dose.

Thought Questions:

What are additional factors to consider when initiating a medication trial in a child with developmental disabilities? What resources can provide information on medication?

THE ROLE OF MEDICATIONS

Children with developmental disabilities are frequently treated with drugs, often more than one at the same time. Therefore, it is very important to understand the role of medications in this patient population. Children can be treated prophylactically to prevent exacerbations; for example, glycerol phenylbutyrate is used to prevent hyperammonemic episodes in the management of urea cycle disorders (Berry et al., 2017; see Chapter 16). Medications are also used to treat symptoms associated with certain medical conditions; for Isaac, baclofen was used to treat his spasticity caused by cerebral palsy (Goyal, Laisram, Wadhwa, & Kothari, 2016). Both desired and undesired effects of a medication largely depend upon the concentration of the drug at the site of action (e.g., liver, lung, or brain). This is determined by 1) how the drug is absorbed by the gut (e.g., if taken orally), 2) how it is distributed in the body to different tissues, 3) how it is metabolized (i.e., most often via the liver), and 4) how it is eliminated by the body (i.e., most often via the kidneys). In addition, variations among people can also cause differences in drug concentrations. These differences include age, disease, concomitant medications, and genetics (see Factors Impacting Drug Concentrations; de Wildt et al., 2014; Kearns et al., 2003; van den Anker, 2010). The amount of drug needed for clinical effectiveness varies widely between children and adults and requires individualization of dosing regimens.

WHEN TO START MEDICATIONS

The decision to begin medication(s) takes place when nonpharmacological treatments (if available) have been optimized or exhausted. In the case of Zachary, the decision to start medications for his ADHD has been delayed because he had not yet undergone behavioral therapy. When beginning treatment with medication, it is important to understand 1) the treatment goals, 2) the monitoring parameters, and 3) the risks associated with taking the drug. Treatment goals and end points should be established when starting drug therapy and should be evaluated on a periodic basis during treatment; these can include cessation of symptoms (e.g., baclofen to treat spasticity) or prevention of disease symptoms (e.g., levetiracetam to prevent seizures). Medications also need to be monitored; some can be monitored using a basic clinical examination, whereas others require more intense monitoring such as **therapeutic drug monitoring** (the clinical practice of measuring specific drug concentrations in blood samples at designated intervals to ensure a therapeutic concentration in a patient’s bloodstream), liver function tests,

complete blood counts, and metabolic panels (Gerlach et al., 2016; Kang & Lee, 2009). **Adverse drug reactions (ADRs)**, which are an unintended response to a drug that occurs at standard doses used in the treatment or prevention of a specific disease, can also occur. Some ADRs are dose related (e.g., baclofen and drowsiness), and others are paradoxical (e.g., diphenhydramine causing excitability in some children instead of the intended drowsiness). In addition, children are more prone to ADRs than adults due to differences in drug disposition (Elzagallaai et al., 2017; Garon et al., 2017).

When starting medications in children, the general rule of thumb is “start low and go slow” (Pejovic-Milovancevic et al., 2011, p. 315). This means starting drug therapy at the lowest possible dose and then titrating up slowly until the desired effects are seen. This also minimizes the risk of ADRs. The general rule does not apply during critical illness, such as sepsis or status epilepticus, where aggressive and prompt treatment is necessary. A second important point is that when considering starting additional medications, it is important to first optimize current drug therapy because **polypharmacy** (the use of multiple drugs by a single patient to treat one or more conditions) also increases the risk of ADRs (Dai, Feinstein, Morrison, Zuppa, & Feudtner, 2016). Children with disabilities typically take more medications compared with typically developing children. As a result, attention must be paid to maximize the effects of the medication while minimizing the number of prescribed drugs and attendant risk of side effects (Box 38.1). Therefore, it is important to define treatment goals prior to starting medications to ensure effective drug therapy and understand the risk-benefit ratio of the medication.

FACTORS AFFECTING DRUG CONCENTRATIONS

A number of factors can impact drug concentrations and effectiveness, including developmental pharmacology; drug, disease, and food interactions; and pharmacogenomics. Each of these factors is discussed in the sections that follow.

Developmental Pharmacology

Infants and children are inherently different from adults in terms of behavioral and medical perspectives. The developmental changes in children remarkably affect their **pharmacokinetics** (the absorption, distribution, metabolism, and excretion of drugs; i.e., what the body does to the drug) and **pharmacodynamics** (the biochemical and physiological effects of drugs; i.e., what the drug does to the body; de Wildt et al., 2014; Kearns et al., 2003; Mulla, 2010; van den Anker, 2010). Developmental changes in various organ systems that affect pharmacokinetics (e.g., changes in gastric pH, body fat composition, maturation of the gastrointestinal system, changes in drug metabolizing enzymes in the liver, and renal function changes as the child develops) require medications to be periodically adjusted. Pediatric dosing **nomograms** (charts showing scales for drug dosage) are available for many drugs that are broken down by age groups and body weight (Anderson & Holford, 2013). Developmental changes in pharmacodynamics also play a role in the adjustment of medication as biological systems evolve from birth. This is especially important in the treatment of children with disabilities, because many medications affect the central

BOX 38.1 INTERDISCIPLINARY CARE

Role of the Outpatient Pharmacist in Medication Management

The role of the pharmacist has expanded since the late 1980s, most notably in the area of medication therapy management. Though this has mostly focused on the care of chronic adult conditions (Brahm & Brown, 2004), pharmacists can also play a vital role in the care of children with disabilities (Gray et al., 2017). Outpatient pharmacists in the clinic and retail setting are a valuable resource in helping to optimize medications in these children. Every prescription sent to a pharmacy is verified by a pharmacist: They check to see if 1) the dose is correct and 2) there are no interactions with any other medication the patient is concurrently taking. Pharmacists in this setting also counsel patients and families on the best way to take medications (e.g., take with a fatty meal or avoid taking with calcium-containing products). Finally, they make recommendations to physicians and other health care providers on alternative medication therapies and different formulations, and they can administer vaccinations in the outpatient setting (Abraham, Brothers, Alexander, & Carpenter, 2017; Deshpande, Schauer, Mott, Young, & Cory, 2013). As children who are medically complex live longer, outpatient pharmacists serve as valuable members of the health care team in their optimal management.

nervous system (CNS), which grows rapidly from birth. These changes can cause a paradoxical effect or require higher doses to achieve therapeutic clinical end points (Mulla, 2010). For example, digoxin is used in children with congenital heart disease to prevent arrhythmias, and they require higher doses compared with adults to achieve the same clinical response due to changes in the heart muscle over time (Hastreiter, van der Horst, Voda, & Chow-Tung, 1985; Wells, Young, & Kearns, 1992; Wettrell & Andersson, 1977). Another example is the use of benzodiazepines in preterm infants and neonates. Benzodiazepines are typically used to abort seizures; however, their use in preterm infants and neonates can cause seizures because of developmental changes in the GABA receptor, which is involved in inhibitory signals in the brain (Andersen et al., 2002; Brooks-Kayal & Pritchett, 1993; Chugani, Kumar, & Muzik, 2013). Therefore, the developmental changes in children require periodic monitoring and dose adjustment to maximize efficacy and minimize toxicity.

Drug, Disease, and Food Interactions

Sometimes when there is **polypharmacy**, medications can interact with each other causing **drug–drug interactions**, which are a change in a drug's effect when taken together with another drug due to changes in pharmacokinetics. This can lead to overexposure and toxicity or underexposure and subtherapeutic effects. For example, erythromycin is an antibiotic for treatment of infections and also a commonly used gastrointestinal motility agent for patients with CNS disorders, such as HIE and traumatic brain injury (TBI). Erythromycin can also inhibit an important drug-metabolizing enzyme (CYP3A4) and increase drug levels of medications that use that enzymatic pathway; this may

require a decrease in that drug's dose while concomitantly receiving erythromycin (Dai et al., 2016; de Wildt et al., 2014; Zhou, Xue, Yu, Li, & Wang, 2007). Another example is phenobarbital; this medication is frequently used in the treatment of seizures in neonates with HIE and as an adjunctive therapy for pediatric epilepsy (Glauser et al., 2016; National Clinical Guideline Centre [UK], 2012). In addition, phenobarbital can induce multiple drug-metabolizing enzymes, which can lead to decreased concentrations of drugs that utilize those pathways and result in subtherapeutic levels of drugs (de Wildt et al., 2014; Zhou et al., 2007).

There also can be **drug–disease interactions**, which are a change in a drug's effect due to a disease state that affects drug metabolism or absorption. As with drug–drug interactions, these drug–disease interactions can cause either elevated or decreased drug concentrations, which can lead to ADRs or subclinical benefits. Children with disabilities are more frequently hospitalized than their typically developing peers; this is especially relevant because critical illnesses can also affect drug metabolism and thus the efficacy of drugs. For example, older pediatric patients with methylmalonic acidemia (a type of inborn error of metabolism) have impaired renal function; thus, their medications have to be adjusted because of the decreased elimination of drugs through the kidney (Zsengellér et al., 2014). Patients with trisomy 21/Down syndrome often have congenital heart defects that may be associated with a prolonged QT interval on an electrocardiogram (Tisma-Dupanovic et al., 2011). Certain medications can also prolong the QT interval, such as azithromycin for pneumonia. Heart arrhythmias are more likely to occur if patients with an already prolonged QT take medications that can further increase it (Ayad, Assar, Simpson, Garner, & Schussler, 2010; Box 38.2).

BOX 38.2 INTERDISCIPLINARY CARE

Role of the Inpatient Pharmacist

Children with medically complex needs are living longer lives, but they have increased risks of infections and other comorbidities that frequently require hospitalization. For example, children with cerebral palsy are frequently admitted for aspiration pneumonia that can require intravenous antibiotics. In addition to treating their acute problem, medications for their chronic conditions must be continued. One of the responsibilities of a clinical (inpatient) pharmacist is to ensure seamless transitions of care (outpatient to inpatient and vice versa; Zhang, Zhang, Huang, Luo, & Wen, 2012). Also, clinical pharmacists typically will conduct rounds with the interprofessional medical team, intervene on possible adverse drug reactions, recommend dosing for therapeutic drug monitoring, and suggest alternatives when first- or second-line therapies fail. Evidence shows that increased pharmacist presence in the hospital is associated with substantially improved care of critically ill children and that they are a valuable member of the medical team (Dai et al., 2016).

Finally, there can be drug–food interactions, which are a change in a drug’s effect due to the interactions with foods, beverages, or supplements. Like the other interactions, certain foods can increase or decrease drug concentrations in the body. Parents may unknowingly be giving medications to their child with food that may negatively impact the effectiveness of the medications (Deng et al., 2017; Schmidt & Dalhoff, 2002). For example, ciprofloxacin is a commonly prescribed antibiotic that is used for respiratory infections, such as aspiration pneumonia. However, calcium in food products (e.g., milk, formula, and even calcium-fortified orange juice) can bind ciprofloxacin and decrease its absorption; this can lead to decreased drug concentrations in the body and treatment failure (Neuhofel, Wilton, Victory, Hejmanowski, & Amsden, 2002). Children with trisomy 21 are at increased risk for hypothyroidism and need to take levothyroxine to correct their thyroid dysfunction (Lavigne et al., 2017). This drug is best taken on an empty stomach with a small glass of water. If taken with food or another beverage, it can greatly decrease the absorption of levothyroxine and lead to subclinical outcomes (Geer, Potter, & Ulrich, 2015).

In sum, children with disabilities often have chronic conditions that require the long-term use of medications. Medications can have drug–drug, drug–disease, and drug–food interactions, and therefore it is important to routinely assess concomitant medication therapy and drug administration techniques during each clinic visit and patient encounter. Clinical outcomes from medications can be maximized and ADRs can be minimized by taking the time to evaluate how the patients are taking their medications.

Pharmacogenomics

Genes also play an important role in an individual’s response to drugs. **Pharmacogenomics**, the study of how genes affect a person’s response to drugs, helps us understand genetic variations between people to predict a drug’s appropriate dose and clinical effectiveness. Pharmacogenomics helps to explain why a drug may be effective in some people but fail to benefit others. In some cases, patients who fail treatment may also experience serious ADRs. These genetic variations are called **polymorphisms** (the occurrence of multiple phenotypes in a population; Ahmed, Zhou, Zhou, & Chen, 2016; Sissung et al., 2017). For example, children with autism may be prescribed antidepressants to treat repetitive behaviors and social anxiety. However, these drugs can be affected by different polymorphisms of drug-metabolizing enzymes; these polymorphisms can either decrease drug concentrations (and decrease clinical efficacy) or increase drug concentrations (and cause

ADRs; Sissung et al., 2017). Another example is with baclofen and the treatment of spasticity. In the case of Isaac, baclofen was effective in treating his symptoms; however, baclofen does not achieve the same clinical response in all patients due to the pharmacogenomic variability in baclofen drug metabolism (McLaughlin et al., 2018).

Pharmacogenomics can also contribute to ADRs. As mentioned earlier, ADRs can either be classified as 1) dose dependent or 2) paradoxical. It is hypothesized that some paradoxical ADRs occur due to drugs binding to off-target receptors; thus, patients with a certain polymorphism may be at more risk for ADRs. For example, carbamazepine is a commonly used drug in the treatment of epilepsy; this medication can cause an ADR called Steven-Johnson syndrome (a severe type of immune-skin reaction where the surface layers of skin and mucous membranes blister and peel). It is strongly associated with the HLA-B*15:02 allele, especially in the ethnic Han Chinese population where this polymorphism is highly present (Garon et al., 2017).

Although there have been many recent advances in pharmacogenomics, there is still a lack of clinical applicability (Chang, McCarthy, & Shin, 2015). Despite this, there is a great potential in improving treatments using pharmacogenomics, especially in the area of behavioral health. Children with disabilities often require these types of medications, and they are administered in a trial-and-error approach to find the medication with the greatest benefit and least side effects. A pharmacogenomics-guided treatment approach can reduce costs and time to achieve effective treatment and outcomes (Valdes & Yin, 2016; Box 38.3).

FACTORS AFFECTING DRUG ADMINISTRATION

The formulations of medications and the routes by which they are administered are important considerations and potential challenges when administering drugs in the pediatric population.

Formulations

In adults, medications are fixed at set doses, typically as single- or multiple-strength pills (e.g., acetaminophen 500-mg tablet; levetiracetam 250-mg, 500-mg, and 750-mg tablets). However, this becomes problematic in pediatrics because 1) not all children can swallow pills and 2) the doses that are available may be too much for the child. Children, with appropriate training, can learn to swallow pills between 6 and 11 years of age (Jones et al., 2017; Meltzer, Welch, & Ostrom, 2006; Patel, Jacobsen,

BOX 38.3 EVIDENCE-BASED PRACTICE**The Case for the Use of Pharmagenomics in the Treatment of Autism**

Many medications are used in the treatment of autism. For example, risperidone, an atypical antipsychotic, is commonly used to treat irritability associated with autism, albeit with mixed clinical outcomes (Dean, 2012). This medication also has a significant side effect profile, which includes altered cardiac conduction, decreased blood cell counts, cerebrovascular effects, serum lipid abnormalities, extrapyramidal symptoms (movement disorders), hyperglycemia, hyperprolactinemia, priapism, and weight gain (Taketomo, Hodding, & Kraus, 2017). However, not all children with autism taking risperidone experience these side effects. Recent literature has shown associations between drug concentrations of risperidone and 9-hydroxyrisperidone (a metabolite) and certain polymorphisms of CYP2D6 (a drug-metabolizing enzyme involved in the metabolism of risperidone) and drug transporters (Medhasi, Pasomsub, et al., 2016; Medhasi, Pinthong, et al., 2016; Vanwong et al., 2017). Patients with these polymorphisms have elevated levels of drug and thus may be at an increased risk of adverse events, such as hyperprolactinemia (Hongkaew et al., 2015; Ngamsamut et al., 2016). Another study showed a significant association with nonstable clinical outcomes in children with autism who had the Taq1A T-carriers of the dopamine 2 receptor gene (Nuntamool et al., 2017). Together, these studies support the use of pharmacogenomics when using risperidone.

Jhaveri, & Bradford, 2015). However, there will be some children who will have difficulty with swallowing pills or who cannot physically swallow pills due to their disability (e.g., cerebral palsy). Options for children who cannot swallow pills include liquids (e.g., solutions, suspensions, syrups, emulsions), orally disintegrating tablets, chewable tablets, transdermal patches, intranasal sprays, rectal suppositories or enemas, intravenous injections, nebulized liquids, and inhalers. However, all formulations (dosage forms of the medication) do not exist for each medication (Ivanovska, Rademaker, van Dijk, & Mantel-Teeuwisse, 2014). Another problem is that the child may not like a certain formulation of the drug. For example, the child may not like the taste of chewable or disintegrating tablets, which may be bitter (Batchelor & Marriott, 2015). Or, the child may resist receiving the enema or suppository because he or she feels uncomfortable about getting it rectally. All these issues must be taken into consideration when starting medications for children with disabilities.

Another issue with medications for children with disabilities is the dose. Although it may be possible to use a pill cutter to divide the tablet to achieve the correct dose (e.g., if the levetiracetam dose needed is 125 mg, half of a 250-mg tablet may be used), this technique will not always work when doses are not half or a quarter of a tablet size. Furthermore, medications may not be available as a tablet but only as a formulation that cannot be cut, such as a capsule or an **extended-release** formulation that allows the drug to be slowly released over a period of time (this formulation will lose its effectiveness if it is crushed or cut). As discussed earlier, for non-life-threatening situations, medical professionals

should slowly titrate up the dose to maximize the beneficial effect while minimizing ADRs; this may not be possible with tablets. In the case of Isaac, his starting dose of baclofen was 1.1 mg. Baclofen tablets are only available as 5-mg and 10-mg tablets; it would be difficult to cut a 5-mg tablet into a 1.1-mg dose. Instead, his physician would prescribe a liquid formulation that could be easily and accurately measured in a syringe.

Finally, the commercial availability of some formulations presents a challenge. In the case of Isaac, there is a commercially available baclofen oral suspension that he could use (i.e., his family could pick it up at any pharmacy). However, this baclofen suspension became commercially available in 2016. If Isaac had started baclofen before 2016, his parents would have needed to get his baclofen at a **compounding pharmacy** (a special pharmacy that can make drug formulations that are specifically tailored to patients such as liquid suspensions, suppositories, and creams). It is important to note that not all retail pharmacies are compounding pharmacies; this presents a barrier to patient and their families in obtaining these compounded medications, especially in more rural areas. Further complicating the problem is that these compounded medications typically have shorter shelf-lives than commercially available medications (Batchelor & Marriott, 2015; Ivanovska et al., 2014). For example, children with maple syrup urine disease (an inborn error of metabolism, see Chapter 16) are treated with supplements of valine and isoleucine. These amino acids are only commercially available as a powder, and it is often compounded into an oral solution for ease of administration. In addition, the shelf-life of compounded valine and isoleucine oral

solutions is only 14 days (United States Pharmacopeia, 2017), which means that the family would need to pick up these medications every 2 weeks from the pharmacy. Formulation issues can present a challenge not only for children with disabilities, but for all children.

Routes of Administrations

Some children with disabilities do not have typical swallowing reflexes (e.g., children with severe cerebral palsy; Martinez-Biarge et al., 2012) or TBI (Popenack, Gray, & Reuter-Rice, 2015). Due to an inability to swallow, they often receive food and medication via **nasogastric tubes** (NG tubes; tubes that reach the stomach through the nasal opening) or **gastric tubes** (G tubes; tubes that are inserted through the abdomen wall directly into the stomach). This presents a challenge when administering oral medications, especially when it is in a solid form such as a tablet or capsule. Routes of administrations, defined as the path a drug is administered into the body, such as oral, intravenous, transdermal, or inhalation, ultimately determines the formulation of the medication.

To complicate the issue, some formulations are not compatible with certain routes of administration. For example, ciprofloxacin (an antibiotic) is available in a commercially available suspension; however, it can clot NG tubes as it is a thick and grainy solution. Instead of using the commercially available suspension, it is recommended to crush and dissolve a tablet to give through an NG tube (White & Bradnam, 2015). Another issue that can arise is if there is a change in the route of administration (e.g., oral to intravenous). A commonly encountered example is oxcarbazepine, a typically prescribed anti-epileptic drug. This medication is only available as a suspension or tablet; if a child with epilepsy is admitted to the hospital and cannot take anything by mouth, oxcarbazepine needs to be switched to a different drug that can be given intravenously. Another instance where a similar challenge may occur is with hydroxocobalamin (vitamin B12) in children with disorders of intracellular cobalamin metabolism (an inborn error of metabolism). Although this vitamin is available as liquid or tablet, children with these disorders require intramuscular injections due to limited oral absorption (Carrillo, Adams, & Venditti, 2017; Green et al., 2017).

Finally, certain routes of drug administration can cause drug interactions; this is most notable with feeding tubes and children with disabilities who require feeding around the clock. As mentioned earlier, certain medications, such as levothyroxine, can have interactions with other drugs or food. It is recommended to hold feeds for at least 1 to 2 hours before and 30 minutes

after drug administration to minimize the interactions with other food or drugs (if applicable). It is also important to flush the tube before and after drug administration to minimize drug binding to the feeding tube (Grissinger, 2013). Like with formulations, being cognizant of the different routes of administration can lead to reducing the risk of treatment failure. In this regard, pharmacists and clinical pharmacologists are important members of the interprofessional team who can provide answers to these types of problems (Boxes 38.1 and 38.2).

OTHER FACTORS TO CONSIDER

Off-Label Use of Drugs

The research and development of the majority of drugs on the markets have focused on adults; consequently, the data proving safety and efficacy for these medications are all based on adult data. These clinical trials often excluded infants, children, adolescents, and pregnant women, as they are considered vulnerable populations. This means that many drugs given to infants, children, and adolescents are used **off label** (an unlabeled use of an approved drug). On label means that the use is listed in the package insert of the drug (i.e., approved by a regulatory agency such as the U.S. Food and Drug Administration). The absence of an indication on the drug label does not necessarily mean it would be wrong to use it in a certain age group or for a particular disorder. However, it means that there may be a lack of sufficient evidence, as determined by a regulatory agency, to be included as an approved use in the label (Frattarelli et al., 2014; Ito, 2017). This concept is especially important because many children with disabilities are often prescribed medications off label, especially in the case of psychotropic medications (Bruni et al., 2018; Kearns & Hawley, 2014; Sharma et al., 2016). When prescribing medications off label, current literature should be used to evaluate the risks and benefits as well as duration of therapy and incidence of adverse effects. It is also important to note that some medications are prescribed off label with minimal evidence because that drug has been entrenched in clinical practice. In the case of Isaac, he was prescribed oral baclofen to treat his hypertonicity. However, there is mixed efficacy regarding the use of oral baclofen in this patient population (Navarrete-Opazo, Gonzalez, & Nahuelhual, 2016). Finally, finding strong evidence can be challenging as it is hard to design clinical trials involving children with disabilities. It may be acceptable to use medications off label, but it is important for the physician to critically evaluate the literature on a periodic basis to see if better treatment options exist.

Use of Complementary Health Approaches

The use of **complementary health approaches (CHA)** is widespread (Tsourounis & Dennehy, 2015), especially among families of children with disabilities and particularly in children less than 1 year of age (Harris, 2005; Provenzi, Barello, Saettini, Scotto di Minico, & Borgatti, 2017; see Chapter 39). CHA are health and wellness therapies that are not typically part of a conventional Western medicine. Complementary medicine are treatments (e.g., megavitamins) combined with conventional medicine, whereas alternative medicine are treatments used in place of conventional medicine. Families may be reluctant to mention the use of CHA to the health care providers because of the negative connotations in the medical community. Further compounding the problem is that many clinicians also do not ask patients and their families regarding CHA use during patient visits (Gaylord & Mann, 2007). As stated earlier, supplements, nutraceuticals, and other CHA-related products can negatively interact with other drugs, either decreasing the efficacy of medications and/or increasing the likelihood of ADRs. For example, *Bacopa monnieri*, or the waterhyssop, is an Ayurvedic herb that is believed by some to improve cognition and behavior in children and adults (Kean, Downey, & Stough, 2016), and it is sometimes used by families with children with autism. However, this herb can inhibit drug metabolizing enzymes and potentially lead to ADRs when taken with other medications that utilize this pathway (Ramasamy, Kiew, & Chung, 2014). Another issue is evidence of the lack of efficacy of many CHA. CHA are started by families in the belief that they will help their child; some are started as a result of cultural beliefs, whereas others may be started due to word of mouth from other families with the disorder based on anecdotal evidence (Bang et al., 2017; Smolinske, 2017). As an example, a deficiency in omega-3 polyunsaturated fatty acids has been found in some children with autism and ADHD (Agostoni et al., 2017). Parents may give omega-3 fatty acids supplements to their children in the hope of helping neurocognitive development, but current evidence shows a lack of efficacy (Agostoni et al., 2017). Finally, it is important to know that supplements and CHA products are not as tightly regulated by the FDA as medications. This lack of federal oversight can lead to misbranded (not containing ingredients stated), tainted (containing unlisted ingredients), or adulterated products (containing unsafe ingredients; Abdel-Tawab, 2017; Humbert & Kornspan, 2017). Therefore, it is imperative that discussions of CHA use be included in every patient visit to ensure optimal pharmacotherapy outcomes.

Role of Vaccines

Although not typically thought of as a medication, vaccines play an important role in the health and well-being of children with disabilities. Immunization is a cost-effective method that prevents many common childhood diseases and is one of the greatest public health achievements of the 20th century. Although commonly associated with infancy, since 2005 there have also been new adolescent vaccines that have come to the market that are recommended by the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (2017). Children with disabilities experience many adverse health outcomes and are at greater risk for infections (e.g., children with Down syndrome); thus, vaccinations provide an effective and economical health benefit. However, literature suggests that vaccine coverage in adolescents and young male children with disabilities is lagging. Potential strategies for increasing compliance include scheduling vaccinations at existing medical visits, having all members of the health care team be responsible for vaccinations, and approaching the subject of vaccination at every patient encounter (McRee, Maslow, & Reiter, 2017; Reiter & McRee, 2016; Walmsley, 2011). Everything considered, low levels of vaccination coverage in the population are missed opportunities for optimal health outcomes, and all members of the health care team should be actively involved to ensure coordinated care.

Drug Costs and Medical Insurance

In countries where universal health care does not exist, drug expenditures are a significant financial burden for families of children with disabilities. These families have health care costs that are three times higher than families with typically developing children, and they experience much higher out-of-pocket costs (Newacheck & Kim, 2005). These financial barriers can force families to decide between medications and other essential living expenses, such as food and housing (Berkowitz, Seligman, & Choudhry, 2014). However, when families must forgo the purchase of needed medication, it can lead to suboptimal outcomes and costly hospitalizations for their child with disabilities (Coller et al., 2014). Families also can be underinsured and may have high deductibles, which can limit medication purchases (Committee on Child Health Financing, 2014; Szilagyi, 2012). There are mechanisms and assistance available to families to help with out-of-pocket costs such as copay cards, drug assistance programs, and government-subsidized insurance for children (e.g., Children's Health Insurance Program [CHIP]; see

Chapter 41). For that reason, it is important to evaluate the ability of families to obtain medications without significantly affecting their financial situations at every medical visit.

Communication and Medication Adherence

Both written and verbal communication are an important part of health care. Effective communication contributes to **adherence** (also known as compliance; it is the degree to which a patient correctly follows medical advice and/or takes their medication). This can increase patient safety, clinical outcomes, and overall satisfaction (Yin et al., 2010). Once the patient leaves the medical visit, the health care team must rely on the parent and child to ensure appropriate dosing and administration. Therefore, it is imperative that the health care team clearly communicate to the family how to properly take the medication and explain why it is needed (Berrier, 2016). **Health literacy** (the degree to which individuals have the capacity to understand basic health information in order to make appropriate and informed decisions) and parental beliefs also play an important role in adherence. This is especially critical in cases when parents may not fully comprehend the role of their child's medication or when parents hold cultural beliefs that conflict with the prescribed therapy (Cohen, Dillon, Gladwin, & De La Rosa, 2013; Johnston, Seipp, Hommersen, Hoza, & Fine, 2005). For example, parents may withhold drugs because they believe medications cause more harm than good (e.g., parents may refuse anti-epileptic drugs and as a result the child experiences more seizures). Conversely, parents may jump to the conclusion that a medication can cure their children without any further intervention (Schwartz & Axelrad, 2015). In conclusion, open and honest communication between medical providers and families of children with disabilities will promote medication adherence and effective clinical outcomes.

SUMMARY

- Medications should be started when nonpharmacological options have been maximized.
- When starting medications in non-life-threatening situations for children with disabilities, it is best to "start low and go slow." This will help to reduce ADRs.
- There are many factors that can impact drug concentrations. It is important to periodically adjust medications and talk with patients and families about how they are taking their medication.
- Many medications in children with disabilities are often given off label. Critically evaluating the literature prior to and during treatment is important.
- CHA is growing in use. Many of these treatments are benign, but some can cause harm or decrease the efficacy of concomitant medications.
- Medication adherence is the responsibility of the patient, family, and medical team. Assessing adherence on a consistent basis will help to maximize drug outcomes.
- Pharmacists and clinical pharmacologists can be valuable team members in the care of children with disabilities by providing expert drug advice and recommendations.

CHAPTER 39

Complementary Health Approaches

Thomas D. Challman

Upon completion of this chapter, the reader will

- Understand the types of complementary health approaches currently being used in children with disabilities
- Be able to discuss the evidence base for various complementary health approaches
- Understand how to counsel families effectively regarding the use of these therapies

Caregivers of children with disabilities—and the health care practitioners who provide medical care for these children—often hear about therapies, whether via the Internet, social media, or word of mouth, that are promoted as beneficial for some aspect of a child’s developmental or behavioral functioning. They may also read about these therapies in peer-reviewed journals (Kemper, Gardiner, & Birdee, 2013; Levy & Hyman, 2017). The evidence base used to justify these therapies is commonly suboptimal; as such, rational strategies are clearly needed to help make sense of this information.

In many medical conditions in which there are no highly effective treatment approaches, therapies that may have limited plausibility and a weak evidence base may gain popularity. This phenomenon has emerged in the field of developmental disabilities because caregivers of children with disabilities have a desire to pursue treatments that they feel might be helpful. Care must be taken, however, to guard against ineffective or pseudoscientific treatments that create the potential for harm—physical, emotional, or financial. Importantly, the ethical principles of beneficence,

nonmaleficence, autonomy, justice, and truthfulness need to be included within a framework that caregivers and medical providers use to critically analyze whether a particular nonstandard therapy should be supported or discouraged.

■ ■ ■ CASE STUDY

Stephen is a 3-year-old boy who presented to his pediatrician at the age of 2 years with language delay, decreased social responsiveness, and various repetitive behaviors. His behavioral and developmental features satisfied criteria for a diagnosis of autism spectrum disorder (ASD). Intervention services were initiated—speech-language therapy and behavioral therapy based on the principles of applied behavior analysis. His pediatrician also ordered fragile X DNA analysis and chromosomal microarray, which were normal. His parents return with additional questions. A friend, who also has a child with ASD, told them about a nutritional supplement and special diet that can improve a child’s language skills and social behavior. Stephen’s parents did additional reading about these and other therapies

on the Internet, and they are looking for guidance about whether to use these therapies in their son.

Thought Question:

How should pediatricians address parents' questions about complementary health approaches?

HISTORY, DEFINITIONS, AND DESCRIPTIONS

Various definitions have been used to try to demarcate nonstandard therapies from conventional or accepted medical practices. The term *complementary and alternative medicine* enjoyed a period of popularity and had various definitions, including the following:

- “Interventions not taught widely in medical schools or generally available at U.S. hospitals” (Eisenberg et al., 1993, p. 246)
- “Diagnosis, treatment and/or prevention which complements mainstream medicine by contributing to a common whole, by satisfying a demand not met by orthodoxy or by diversifying conceptual frameworks of medicine” (Ernst et al., 1995, p. 506)
- “A broad domain of healing resources that encompasses all health systems, modalities, and practices and their accompanying theories and beliefs, other than those intrinsic to the politically dominant health systems of a particular society or culture in a given historical period” (O'Connor et al., 1997, p. 50)
- Practices that are “not presently considered an integral part of conventional medicine” (National Center for Complementary and Alternative Medicine, 2000, p. 8)

More recently, the term **complementary health approaches (CHA)** has been used to describe treatments that fall outside the mainstream of standard medical care and the term **integrative medicine** has been used to describe the concept of using standard and nonstandard therapies in a coordinated manner (National Center for Complementary and Integrative Health, 2016). The National Center for Complementary and Integrative Health (NCCIH), a National Institutes of Health center established for the purpose of studying complementary health approaches, categorizes these practices into two main domains—natural products (including botanical agents, vitamins, minerals, and special diets) and mind-body practices (such as massage therapy, yoga, chiropractic, and acupuncture). It is important to note that any dichotomy between CHA and conventional medicine may be a false one—ultimately,

therapies either have some degree of effectiveness or they do not, and what we should be most attentive to is the evidence that supports or refutes the plausibility and efficacy of a particular treatment. A treatment that initially gains popularity as a complementary health approach can, and should with the development of a sufficient body of evidence of effectiveness, migrate into the realm of accepted medical practice—although thus far this has been an infrequent occurrence.

The use of CHA is common among adults and children. The first national survey to determine patterns of use of these therapies showed them to be employed commonly among adults in the United States (Eisenberg et al., 1993), with approximately one third of the respondents reporting the use of at least one nonstandard therapy during the prior year. Subsequent studies have also indicated that the use of nonstandard therapies is common among adults (Barnes, Powell-Griner, McFann, & Nahin, 2004; Posadzki, Watson, Alotaibi, & Ernst, 2013; Stussman, Black, Barnes, Clarke, & Nahin, 2015) and children (Black, Clarke, Barnes, Stussman, & Nahin, 2015; Davis & Darden, 2003; Yussman, Ryan, Auinger, & Weitzman, 2004). In the 2012 National Health Interview Survey, the overall prevalence of CHA use among children ages 4–17 years in the United States was 11.6%. The rate of nonstandard therapy use is increased in children with chronic medical conditions (Adams et al., 2013; Magi et al., 2015), and among children with developmental disabilities or mental health concerns. Estimates of the prevalence of CHA use in children with ASD range from 28%–54% (Akins, Krakowiak, Angkustsiri, Hertz-Picciotto, & Hansen, 2014; Höfer, Hoffmann, & Bachmann, 2017; Perrin et al., 2012; Salomone et al., 2015). Frequent use of CHA has been demonstrated in other developmental or mental health disorders, including 30% in children with non-ASD developmental disabilities (Akins et al., 2014); 28.9% in children with attention-deficit/hyperactivity disorder (ADHD), anxiety, or depression (Kemper et al., 2013); and 26.8% in children with cerebral palsy (Majnemer et al., 2013). In multiple studies, an association between higher levels of parental education and nonstandard therapy use in children has been demonstrated (Akins et al., 2014; Davis, Meaney, & Duncan, 2004; Sawni-Sikand, Schubiner, & Thomas, 2002).

TREATMENT, MANAGEMENT, AND INTERVENTIONS

What Does the Evidence Show?

Scientific evidence has a hierarchy (Oxford Centre for Evidence-Based Medicine, 2009), which is an essential point to remember when weighing evidence for or against the efficacy of specific CHA in the treatment of

children with disabilities. As with conventional health practices, CHA should be evaluated with clinical trials that include known doses of intervention, randomization, clinical characterization of patients, and appropriate control groups. These design factors are necessary to interpret studies that are large enough to support statistical interpretation. In this chapter, discussion of specific CHAs relies on reviews and/or meta-analysis rather than case reports.

Natural Products

Natural products include interventions such as herbs and other supplements, vitamins, and special diets.

Supplements and Vitamins Melatonin has been used to target sleep problems in children with developmental disorders, and there is a reasonable amount of published evidence that it is effective for shortening sleep latency and increasing total sleep time in children with disabilities (Schwichtenberg & Malow, 2015; Box 39.1). Omega-3 fatty acids are among the most widely used natural product in the pediatric population. However, evidence is currently inconclusive whether polyunsaturated fatty acids have specific therapeutic benefit in children with ADHD or specific learning disorders (Gillies, Sinn, Lad, Leach, & Ross, 2012; Tan, Ho, & The, 2016). Vitamin B6 and magnesium have also been studied as a treatment for ASD, but the evidence remains inadequate to recommend their use (Nye & Brice, 2009).

Special Diets Various special diets have been promoted in the treatment of ADHD, ASD, and other developmental disorders. The **Feingold diet** (Feingold, 1975) became popular in the 1970s based on the theory that certain food additives contribute to the symptoms of ADHD. Controlled trials of this diet have not shown any clear efficacy. Although some studies have

suggested some benefit of an elimination diet (Pelsser et al., 2009; Sonuga-Barke et al., 2013), specific special dietary manipulations are not currently a recommended treatment approach in children with ADHD (American Academy of Pediatrics, Subcommittee on Attention-Deficit/Hyperactivity Disorder, Steering Committee on Quality Improvement and Management, 2011). Likewise, despite the popularity of the gluten- and casein-free diet in children with ASD, the scientific literature currently does not indicate that this diet is efficacious for any of the core symptoms (Hyman et al., 2016; Sathe, Andrews, McPheeters, & Warren, 2017), although it may improve some gastrointestinal symptoms reported in children with ASD (Levy & Hyman, 2017).

Hyperbaric Oxygen Therapy Hyperbaric oxygen therapy (HBOT) has also been used as a treatment for children with cerebral palsy, ASD, and other developmental disorders based on the hypothesis that supranormal oxygen concentrations can heal damaged or dormant brain tissue. The biological plausibility of this idea is weak, and experimental evidence that HBOT is beneficial in the treatment of any developmental disability is lacking. Adverse effects of HBOT, such as barotrauma, can occur. The available scientific literature currently does not support the use of HBOT in children with ASD (Xiong, Chen, Luo, & Mu, 2016).

Mind–Body Practices

As defined by the NCCIH, this group of therapeutic approaches include therapies such as biofeedback, acupuncture, massage, meditation, relaxation techniques, spinal manipulation, yoga, and energy-based practices such as Qi Gong and therapeutic touch. Current evidence does not support a clear role for these treatment approaches in the management of children with disabilities.

BOX 39.1 EVIDENCE-BASED PRACTICE

Melatonin for Sleep Problems in Children with Autism Spectrum Disorder (ASD)

Sleep problems, including prolonged sleep latency and nocturnal awakenings, are extremely common in children with developmental disabilities, including ASD. Melatonin, a hormone produced by the pineal gland, has been studied as a possible treatment for these types of sleep disturbances. A number of studies have shown that melatonin can be effective in shortening the sleep latency and increasing the total sleep duration in children with ASD, although the overall degree of these effects is modest. Although behavioral strategies, including good sleep hygiene practices, remain the first-line approach for sleep problems in children with disabilities, clinicians can consider melatonin as an adjunctive treatment.

Source: Cuomo et al. (2017).

Meditation and Massage Short-term improvements in certain behavioral, language, or sensory measures have been observed in some studies of meditation or massage in children with disabilities. A systematic review of studies of massage therapy for children with ASD highlighted the high risk of bias in these studies and suggested that no firm conclusions could be reached regarding the effectiveness of this therapy in this population (Lee, Kim, & Ernst, 2011). Likewise, in a meta-analysis of studies of massage therapy administered to premature infants, benefits on weight gain and length of stay were demonstrated, but there were no clear differences in neurobehavioral functioning (Wang, He, & Zhang, 2013).

Sensory Integration Therapy Sensory integration dysfunction, more recently referred to as sensory processing disorder, was initially proposed as a theory in the 1970s (Ayres, 1972). This theory is based in the notion that inefficient and disorganized responses to sensory input to the brain is linked to many developmental and behavioral symptoms. Although various sensory-based methods are widely used in the treatment of children with developmental disabilities, particularly ASD, the evidence base to support the use of this therapy remains limited. Several small, short-term studies have indicated improvement in certain sensory measures and motor skills among children receiving sensory-related therapies, although statistically significant benefits in other outcomes were not observed and the risk of bias in these studies was generally high (Weitlauf, Sathe, McPheeters, & Warren, 2017; see Chapter 7).

Music Therapy Music therapy, defined as the use of music interventions to accomplish individualized goals within a therapeutic relationship (American Music Therapy Association, n.d.), has also been used in children with ASD and other developmental disabilities. The largest and most rigorous randomized clinical study of improvisational music therapy (compared with enhanced standard care) in children with ASD showed no significant difference in symptom severity, as measured by the Autism Diagnostic Observation Schedule social affect domain scores, over a 5-month follow-up period, and it did not support the use of this therapy for symptom reduction in this population of children (Bieleninik et al., 2017). Further data are needed to support or refute the role of music therapy in children with disabilities.

Electroencephalographic Biofeedback Electroencephalographic (EEG) biofeedback (neurofeedback) has been investigated as a treatment for conditions

such as ADHD. In this technique, children try to learn to use brain electrical activity to control a computer interface, with the goal of improving ability to sustain attention. Criticism has been raised about the methodologies of some of the early positive studies of this intervention (Heywood & Beale, 2003; Kline, Brann, & Loney, 2002; Ramirez, Desantis, & Opler, 2001). EEG biofeedback is not presently a well-validated treatment approach in children with ADHD (Cortese et al., 2016), although the technique continues to be studied.

Other mind-body practices, including auditory integration training, vision therapy, craniosacral therapy, chiropractic manipulation, and energy-based practices (including therapeutic touch and acupuncture) also have weak theoretical bases, lack sufficient evidence in the scientific literature, and currently have no role in the management of children with disabilities (see Table 39.1).

Counseling Families Regarding Complementary Health Approaches

Many factors attract families to CHA. There is growing societal acceptance of the promotion of wellness through dietary and mind-body practices, and there is a perception that natural approaches are safer and carry fewer adverse effects compared with conventional medical approaches. Families may also welcome the greater control that pursuing therapies in line with their philosophical beliefs affords. Scientific evidence of efficacy may not be an equally weighted factor for families in their decision to pursue CHA. Caregivers and medical providers should be encouraged to consider the following questions when trying to determine the legitimacy of a nonstandard therapy (Lilienfeld, Lynn, & Lohr, 2014; Nickel, 1996). These relate to the theoretical basis for the therapy, the previous scientific evaluation of the therapy, and the methods by which the therapy is promoted. Although therapies should not automatically be discounted simply because they seem unconventional, affirmative responses to any of the following questions should raise a red flag about the legitimacy of a specific nonstandard therapy:

- Is the treatment based on a theory that is overly simplistic?
- Is the treatment based on proposed forces or principles that are inconsistent with accumulated knowledge from other scientific disciplines?
- Has the treatment changed little over a very long period of time?

Table 39.1. Summary recommendations for the use of complementary health approaches in children with disabilities based on current evidence relying on systematic reviews and meta-analyses

	Mind-body practices	Natural products and other biologically based practices
Sufficient evidence exists to support current use	None	Melatonin to shorten sleep latency
More research is needed	Biofeedback, electroencephalography/electromyography Meditation, relaxation techniques Music therapy Massage Sensory integration therapy Transcranial magnetic stimulation	Omega-3 fatty acids Oxytocin
Current evidence does not support use	Chiropractic Auditory integration therapy Vision therapy, visual perceptual training Reflexology Craniosacral therapy Patterning, Doman-Delacato method Acupuncture Energy therapies: therapeutic touch, Reiki, Qi gong Magnet therapy Homeopathy	Pharmacological doses of vitamins (except for the treatment of known metabolic disorders) Gluten-free, casein-free diet in autism spectrum disorder (ASD) Chelation therapy Secretin for treatment of ASD Hyperbaric oxygen for treatment of ASD or cerebral palsy Antiviral agents Immunoglobulins Stem cell therapy

- Is there an absence of well-designed studies published in the peer-reviewed medical literature, or do proponents imply that it is not feasible to scientifically test the therapy?
- Do proponents of the treatment cherry pick data that support the value of the treatment while ignoring contradictory evidence?
- Do proponents of the treatment assume a treatment is effective until there is evidence to the contrary?
- Do proponents claim that a treatment cannot be studied in isolation but only in combination with a package of other interventions or practices?
- Is the treatment promoted as being free of adverse effects?
- Are anecdotes and testimonials used as a primary marketing strategy?
- Do proponents of the treatment use scientific-sounding, but nonsensical, terminology to describe the treatment?
- Is the treatment promoted for a wide range of physiologically diverse conditions? (Adapted with permission from Challman, T. D., & Myers, S. M. [2018]. *Complementary health approaches in developmental and behavioral pediatrics*. In *Developmental and behavioral pediatrics* [2nd ed.]. Itasca, IL: American Academy of Pediatrics.)

Ethical principles need to be considered in any analysis of the use of nonstandard therapies. As outlined above, most of these therapies have very limited evidence to show that they are actually helpful in the conditions for which they are promoted. Beneficence requires that providers remain concerned about the welfare of children with disabilities when considering which therapies to provide or endorse. This same principle also applies to conventional medical practices in the care of children with disabilities—many widely prescribed treatments suffer from an inadequate evidence base to support their use. Likewise, all therapies, conventional and nonstandard alike, carry certain risks. Caregivers and health care providers should be especially wary of potentially harmful nonstandard biomedical interventions, such as chelation therapy (Brown, Willis, Omalu, & Leiker, 2006), which is based on an unsupported theory concerning heavy metals in the etiology of ASD and which has no role in ASD treatment (James, Stevenson, Silove, & Williams, 2015). When considering the safety of nonstandard therapies, providers and caregivers must be cognizant of the principle of non-maleficence, or limiting harm in the quest for achieving an outcome. Whereas direct adverse physical effects from nonstandard biological or manipulative interventions are the most obvious safety concern (Ernst, 2003), attention also needs to be given to other potential negative consequences of nonstandard therapy use, such as increased time and financial demands on a family that lead to inadvertent diversion from interventions

that are known to be effective. At times, the principles of beneficence and nonmaleficence can come into conflict with caregivers' autonomy to choose certain treatments. A challenge for health care providers is to balance these principles, with the understanding that children's health and safety should always take highest priority. Whereas not all providers who promote nonstandard therapies support beliefs that discourage medical interventions known to be beneficial (Wardle, Frawley, Steel, & Sullivan, 2016), the ethical principle of justice dictates that access to services that have proven individual or public health value be maintained even if CHA are being utilized.

Expectancy effects such as the **placebo response**, defined as "a genuine psychological or physiological effect, . . . which is attributable to receiving a substance or undergoing a procedure, but which is not due to the inherent powers of that substance or procedure" (Stewart-Williams & Podd, 2004, p. 326), can explain some or all of the apparent positive effects of specific CHA. Although the use of placebos was common in the 19th century and earlier, this practice fell out of favor because of concerns that their use was dishonest and paternalistic (Edwards, 2005). Even now, however, the use of placebos in standard clinical practice is not uncommon (Harris & Raz, 2012), and a possible role in developmental pediatrics has been suggested (Sandler, Glesne, & Bodfish, 2010). However, using CHA solely to harness some degree of placebo effect can be viewed as deceptive and contrary to the ethical principle of truthfulness.

The American Academy of Pediatrics recommends that providers 1) ask families about the use of different therapies; 2) respect the family's perspectives, values, and cultural beliefs regarding treatment approaches; 3) monitor the patient's response to treatment; 4) establish measurable outcomes when nonstandard therapies are being used; and 5) maintain up-to-date knowledge about currently popular nonstandard therapies (American Academy of Pediatrics, 2008). However, there is not a "one-size-fits-all" approach to counseling families about nonstandard therapy use. Therapies for which there is good evidence of inefficacy, or whose potential harm significantly outweighs any theoretical benefit, should be actively discouraged—chelation therapy in ASD is one such example. There may be some therapies that start as nonstandard and unconventional but ultimately demonstrate effectiveness for a condition using rigorous scientific methodology. These therapies should be moved into the domain of accepted medical practice. An additional group of therapies may have some biological plausibility and warrant further scientific investigation. These approaches should not be recommended until an adequate evidence base of

effectiveness is developed. Lastly, there may be certain therapies that have meaning for a family in the context of a cultural or religious tradition, and it is reasonable for the provider to support the use of these therapies if there are no unacceptable safety risks. The importance of certain cultural and religious traditions has been offered as an argument for why nonstandard therapies should not be marginalized by the scientific community (Kaptchuk & Eisenberg, 2001). However, the reality is that few currently popular nonstandard therapies in children with disabilities have their origin in cultural or religious beliefs (Akins et al., 2014). Health care providers in the medical home have a duty to discuss the scientific rationale, or lack thereof, for CHA with families and to actively discourage those therapies that lack evidence of effectiveness or possess unacceptable risks.

SUMMARY

- The use of CHA is common in children with disabilities.
- Scientific evidence of the efficacy for most natural products and mind-body practices is weak or absent. Rigorous methodology should be used to test specific interventions to determine whether they have a legitimate role in the management of children with disabilities.
- Strong relationships between families and health care providers in their children's medical homes are necessary to build and maintain trust and communication; this will enable families to feel comfortable discussing CHA and be open to provider advice about the scientific validity of these therapies.

PART **VII**

Outcomes

CHAPTER 40

Transition from Adolescence to Adulthood

Lisa K. Tuchman and Cara E. Pugliese

Upon completion of this chapter, the reader will

- Be able to describe the importance of planning for the transition to adulthood for youth with intellectual and developmental disabilities (IDD)
- Understand the relationship among neurodiversity, self-advocacy, self-determination, and health outcomes
- Be knowledgeable about the resources and mandated laws available to assist youth with IDD to move from the home to the community and to the adult health care system
- Know the role of employment and postsecondary education in the transition process
- Understand the increased risks of mental health and behavioral issues and how they may affect the transition to adulthood

Individuals with developmental disabilities encounter the same life transitions as their typically developing peers. Perhaps the most challenging of these is the transition to adulthood, which is a period of complex biological, social, and emotional change. This transition involves moving 1) from school to work and/or postsecondary education, 2) into age-appropriate community inclusion, and 3) from child- to adult-oriented health care. This chapter focuses on approaches to ensuring the successful transition of an individual with developmental disabilities from adolescence to adulthood.

■ ■ ■ CASE STUDY

Elijah is a 22-year-old young man with autism spectrum disorder (ASD) and moderate intellectual disability

(ID) who was born prematurely. He completed his public school education 1 year ago. Elijah currently works at a local supermarket. He receives support and guidance from coworkers who were trained by a local job placement program to provide Elijah with natural supports in the workplace. After work, he participates in some recreational and leisure activities with friends. He goes to the gym and swims regularly at the advice of his pediatrician to promote his general health and prevent obesity. However, he has been told that he needs to find a new physician who cares for adults. He has been relying on his parents to help with this endeavor as he has never had to navigate the health system alone and is unsure of next steps. With his increasing job satisfaction and some financial independence, Elijah has expressed a desire to live on his own this past year. He and his parents contacted the

local Autism Speaks chapter and, with assistance from advocates, found an apartment and a live-in personal-care attendant. Elijah has recently developed a romantic interest in a young person his same age that he met at his job and hopes he can have a relationship with her. He still goes to his parents' house for family dinners and events at least once a week and spends additional time with his two younger siblings, ages 16 and 18, who come to visit him regularly in his apartment.

Thought Question:

What is the role of his pediatric care providers in preparing Elijah and his family for transition to adulthood, including entry into the adult health care system?

GENERAL PRINCIPLES OF TRANSITION TO ADULTHOOD

There are three basic tenets of successful transition from childhood to adulthood for an individual with intellectual and developmental disabilities (IDD). First, transition is a process, not an event. Planning for transition to adulthood should begin as early as possible in late childhood and early adolescence and take into account the young person's increasing autonomy and capacity for making choices (American Academy of Pediatrics, American Academy of Family Physicians, & American College of Physicians Transitions Clinical Report Authoring Group, 2011). Second, coordination among health care, educational, vocational, and social service systems is essential. Third, self-determination and self-advocacy skills should be fostered throughout the transition process. Standards for transition services call for a youth-centered and strengths-based approach, where the young adult acts autonomously as an informed decision maker during the entire transition process to improve his or her quality of life (Walsh, Jones, & Schonwald, 2017; Wehmeyer & Abery, 2013). Ensuring that a young person understands his or her strengths and challenges and can self-advocate for the accommodations needed to be successful and fulfilled is critical to promoting independence and well-being.

MOVING TOWARD INDEPENDENCE: NEURODIVERSITY, SELF-ADVOCACY, AND SELF-DETERMINATION

Just as people can have significant diversity in their physical abilities—some may use their feet to walk, while others may need a wheelchair or cane—individuals also can have significant differences in their cognitive phenotype or thinking styles. The term

neurodiversity has been put forward to describe this spectrum. It was first used by ASD rights advocate Judy Singer and journalist Harvey Blume to propose that ASD was more akin to a neurological difference than a disorder (Armstrong, 2015). This term has since spread beyond the ASD rights movement to the broader disability rights community. The concept of neurodiversity originated as a challenge to previously held views of developmental disabilities as inherently pathological, arguing that neurological differences should be viewed as part of one's personal identity, similarly to gender, ethnicity, and sexual orientation (Ripamonti, 2016). The concept of neurodiversity shifts the focus away from a "cure"—of which there are few currently available for many developmental disabilities—and toward accommodations or supports that will help a person achieve his or her goals and lead a fulfilling life. This is analogous to the approach that the deaf community has been pursuing for decades, but it remains controversial as it also converts the concept of a disorder (often with a discrete cause and potential for treatment) to that of normal diversity.

Self-Advocacy and Self-Determination

Both self-advocacy and self-determination are critical skills to foster throughout the life span for successful transition to adulthood. While the concept of **self-advocacy** has many definitions and, in fact, encompasses an entire civil rights movement of and by individuals with IDD, it generally refers to the ability to effectively understand and communicate one's wants and needs (Test, Fowler, Wood, Brewer, & Eddy, 2005). Self-determination is interdependent with self-advocacy and describes the ability to independently set and pursue one's goals (Shogren et al., 2015). It is critical that transitioning adults are able to understand their own strengths and weaknesses to ensure that they can ask for the necessary supports and accommodations needed to achieve their desired goals. Self-determination tends to increase across the life span and is linked to numerous positive outcomes, including more positive employment experiences, independent living, improved community inclusion, and enhanced quality of life for adolescents with IDD (Nota, Soresi, Ferrari, & Wehmeyer, 2011; Wehmeyer, Palmer, Shogren, Williams-Diehm, & Soukup, 2013).

Wehmeyer and Abery (2013) describe self-determined actions as autonomous, self-regulated, psychologically empowered, and self-realized. Students with ID tend to report lower levels of self-determination than students with learning disabilities, ASD, and emotional and behavioral problems (Mumbardó-Adam et al., 2017). This is often due to their having fewer

opportunities to make choices in their lives rather than to a lack of capacity to become self-determined (Wehmeyer & Abery, 2013). In fact, research indicates that youth with IDD can become more self-determined when given proper supports and direct instruction (see Wehmeyer & Abery, 2013, for a review). Structured intervention to develop self-determination has been shown to be effective in promoting youths' choice-making, problem-solving, decision-making, goal setting, and self-advocacy skills (Cobb, Lehmann, Newman-Gonchar, & Alwell, 2009). Instruction on self-determination and self-advocacy can be taught and supported through guidance from mentors, professionals, family members, self-advocates, and participation in community mentorship programs.

The skills needed for self-determination can also be explicitly shaped incidentally through real-world learning experiences and by an open and supportive acknowledgement of one's disability (Nota, Ferrari, Soresi, & Wehmeyer, 2007). It is vital that youth with IDD understand that everyone has weaknesses and that they will need to ask for supports and mentorship to be successful in reaching their goals at some point in their lives. This often requires direct instruction by the young adult's support team to have the individual verbally identify situations that require self-advocacy and think out loud in order to explicitly model how he/she can self-advocate or ask for help. Families, teachers, and other well-intentioned people often attempt to protect youth with IDD from failing, but it is essential that they understand that, like everyone else, they have strengths and weaknesses. While those weaknesses are not their fault, it is their responsibility to obtain accommodations to ensure that they can be successful in addressing the challenges they will face. Teaching youth to be strong self-advocates across multiple domains—educational, social, health care, and legal—is critical for them developing successful autonomy. Explicit instruction in self-determination is also vital to teach goal setting, planning, and flexible problem-solving. It is especially important in promoting independence and successful goal attainment when obstacles arise. Families and support individuals also can provide encouragement for the individual with IDD to 1) try new experiences; 2) enhance communication and social interactions; 3) make good choices; and 4) learn about their community so they can become an active, contributing member (supporteddecisionmaking.org).

Ultimately, the focus of transitional care for youth with IDD is to help them realize their full adult potential, which includes belonging to a community where they are respected, valued, and able to contribute. It should also be shaped by their present and future personal goals. Many youth with IDD are disconnected

from the community after aging out of the school system. As one example, although nearly 50,000 youth with ASD enter adulthood each year, few have jobs. Youth with ASD from ethnic minorities and low-income groups are further disproportionately affected by poor employment outcomes (Roux, Shattuck, Rast, Rava, & Anderson, 2015). For youth with severe ID, families will usually be able to access services from state departments for developmental disabilities, and the individual is likely to be eligible for long-term services. For youth with mild ID or with typical intelligence but adaptive behavior deficits, adult success or future adult productivity will be dependent on the ability of the individual to learn adaptive and self-advocacy skills.

Teachers and other professionals providing assistance to families can and should begin preparing children with IDD for independence as early as possible. Children as young as 3–5 years of age can begin to incorporate chores into their daily routine. By the developmental age of 6–11 years, children should begin to assume responsibility for their self-care. During adolescence, self-determination skills are focused on identifying and meeting educational/vocational goals and building self-advocacy, including their participation in the **individualized education program** (IEP) process.

MOVING FROM SCHOOL TO WORK

The concept of transition planning originated with schools. As such, education policies are the driving force for almost all aspects of transition. There are five pieces of legislation that outline important educational practices to achieve successful adult outcomes for students with disabilities: 1) the Individuals with Disabilities Education Improvement Act (IDEA) of 2004 (PL 108-446), 2) the School-to-Work Opportunities Act of 1994 (PL 103-239), 3) the Workforce Innovation and Opportunity Act (WIOA) of 2014 (PL 113-128), 4) the Americans with Disabilities Act (ADA) of 1990 (PL 101-336), and 5) the Higher Education Opportunity Act of 2008 (HEOA; PL 110-315). Aspects of these key laws are discussed in the following sections.

Legislation Supporting Transitions for Individuals with Disabilities

The 2004 reauthorization of IDEA in particular has strengthened school-to-work transitions. This legislation established 16 years of age as a clear starting point for transition planning in the IEP. It strengthened the working definition of transition services and redefined transition planning from a statement of needed services to a set of measurable postsecondary goals.

These goals are based upon age-appropriate transition assessments related to training; education; employment; and, where appropriate, independent living skills. This legislation also requires schools to report progress toward meeting transition goals in the IEP. Under IDEA (2004), schools must provide a “summary of performance” to students whose special education eligibility is terminated. This new summary must include information on the student’s academic achievement and functional performance and recommendations on how to assist the student in meeting his or her postsecondary goals. While schools are not required to conduct any new assessments or evaluations in order to provide the summary, they must satisfy the disability documentation required under other federal laws, such as the Americans with Disabilities Act and Section 504 of the Rehabilitation Act of 1973 (<https://www.ncld.org/archives/action-center/learn-the-law/understanding-section-504>). See Chapter 33.

Vocational Rehabilitation

Linking schools with systems of care that serve adults with disabilities, including vocational rehabilitation (VR) agencies, strengthens the transition process. WIOA (2014) specifically aims to increase the access of individuals with disabilities to high-quality workforce services. It prepares them for competitive inclusive employment through mandating training services for individuals with disabilities and structured support for competitive inclusive employment. The WIOA mandates appropriated state funding for transition services to youth with disabilities and supports VR state grant programs

engaging employers to improve participant employment outcomes. Each state has a VR agency that provides employment service supports to people with IDD.

Transition planning as mandated by IDEA (2004) stipulates that if necessary, schools are responsible for bringing in representatives from other agencies, such as VR services, to be part of the transition planning process. VR agencies help pay for postsecondary education for qualified young adults. Box 40.1 gives an overview of the support services VR counselors offer. It is important to note that VR counselors are typically assigned to students only during their last 2 years of school but that parents and students can request VR participation as early as age 14 through One-Stop Career Centers (U.S. Department of Labor, 2005) or the school.

Unlike K–12 education, which is universal, adult services and systems are eligibility based and require that individuals meet established requirements, including financial eligibility criteria. Once individuals are determined to be eligible, the VR agency can provide or arrange for a host of training, educational, medical, and other services designed to help these individuals acquire and maintain gainful employment. Similar to the IEP in the school system, all services aim to develop an individualized plan for employment (IPE; previously called an individualized written rehabilitation program), which is directed at meeting the needs of the young person. Although VR counselors can provide direct services, they more often refer the individual to appropriate community-based agencies. Examples of services covered by VR under an IPE include self-advocacy training, the development of employment-readiness skills, adaptive driving evaluation and

BOX 40.1 INTERDISCIPLINARY CARE

What Is a Vocational Counselor?

A vocational counselor is a professional who assists individuals with disabilities with career-related support. These counselors usually have a master’s-level degree in mental health or community counseling and have knowledge of available employment opportunities suitable for a wide spectrum of interests and abilities. Rehabilitation counseling is a systematic process supporting individuals with physical, mental, developmental, cognitive, and emotional disabilities to achieve their personal, career, and independent living goals in the most integrated settings possible. The counseling process involves communication, goal setting, and supporting self-advocacy. Vocational counselors can implement individualized psychological, vocational, social, and behavioral interventions. Most often vocational counselors work with nonprofit organizations, schools, or other community-based organizations. Working with clients to identify strengths and areas of challenge can help identify and access employment opportunities that meet the individuals’ abilities and strengths. Vocational counselors can also help individuals prepare for interviews, provide resources to hone skills, and support managing expectations. By matching skill sets to jobs, they can help ensure that the individual is successful by finding a job that matches their motivations, goals, and abilities. Many states require that vocational counselors be licensed. For more information, visit <http://www.arcaweb.org/>.

instruction, identification and procurement of assistive technology, supported employment, and customized employment. One area of concern is that while an increasing number of transition-aged adults with ASD are accessing VR agencies, employment outcomes across the United States have not necessarily improved. These adults frequently remain underemployed, earn wages below the poverty threshold, work fewer hours, and earn lower wages than the total population of transition-aged adults served by the VR (Burgess & Cimera, 2014). There is, however, much variability in the success of different state VR programs. For instance, the Autism Society of North Carolina (a VR vendor specifically for adults with ASD) reports an 87% success rate in obtaining competitive employment in 2011, compared with a mean of 33% across the country for the same year (see Burgess & Cimera, 2014). *Accessing Home and Community Based Services: A Guide for Self-Advocates*, which is authored by the Autistic Self-Advocacy Network and the Autism NOW center, may be a helpful resource (<http://autisticadvocacy.org/wp-content/uploads/2014/11/Accessing-HCBS-Guide-v1.pdf>).

Moving Toward Postsecondary Education

Individuals with IDD can take a modified path toward postsecondary education. Many families find it helpful to advocate for their child to remain in the school system until age 21 so that he or she can complete standard diploma requirements or take advantage of vocational experiences or community college classes offered by the public school system. Postsecondary education can take many forms. Although traditionally thought of as college, it may be any form of education or training that takes place after a young adult leaves high school, including on-the-job training, specialized coursework, or even courses through postgraduate study.

For youth, it can be helpful to modify the typical college pathway by beginning postsecondary education at a community college and then transferring to a public or private 4-year college. Many students find it beneficial to reduce their work load by taking fewer classes at a time and completing their coursework over an extended period of time. Online courses can also reduce the social burden and allow the student to work at his or her own pace, although these benefits must be balanced with the student's motivation and ability to work independently. All colleges that receive federal funding have a disability support services (DSS) office. Some colleges and universities have developed more robust and comprehensive support programs for students with ASD and other IDD, and it is important to inquire about the level of supports provided at each institution of interest. It also is important to research

the quality of each institution's programs and make in-person visits to determine an appropriate fit.

There are many students with ASD and average or above intelligence who identify postsecondary education as a primary goal after completing high school. This is the largest group of individuals with IDD who enter college, and therefore this section discusses their experience in some detail. Many of these incoming students are equipped with the cognitive skills to cope with the academic demand of college but struggle with communication and social interactions, executive function difficulties, maintaining motivation, coping with anxiety and stress, self-advocacy, and sensory overload (Adreon & Durocher, 2007; Alverson, Lindstrom, & Hirano, 2015; Trembath, Germano, Johanson, & Dissanayake, 2012; Van Hees, Moyson, & Roeyers, 2015; White et al., 2016). Sosnowy, Silverman, and Shattuck (2018) conducted interviews with parents and young adults with ASD about their postsecondary college experiences. Parents felt that their adult children often needed more holistic services than are available at most colleges. They indicated their need to take an active role in managing their adult child's daily lives in order for them to succeed in college and that organizing supplemental supports (e.g., help with study skills, organization, and socializing/navigating new relationships with school staff and peers) were necessary for their adult child's success. Students felt that, in addition to academic accommodations (e.g., extended time on tests, tutoring, etc.), they thrived when surrounded by staff who promoted autism acceptance and when they found other students they felt they could relate to. Focus groups with secondary and postsecondary administrators, instructors, and educational/academic support staff revealed challenges that are strikingly similar to those identified by students with ASD and their parents in the areas of executive function (e.g., difficulty understanding the big picture and problems with long-term planning and goal setting), self-advocacy, autonomy and self-sufficiency, and establishment and maintenance of long-lasting interpersonal relationships (Elias, Muskett, & White, 2017; Gobbo & Shmulsy, 2014). When families are visiting colleges, they should consider 1) the level of awareness and acceptance of autism, 2) familiarity with factors that promote success, 3) services and accommodations offered by SSD offices, 4) counseling services offered on campus, and 5) specific autism-related supports or programs that may exist on campus. There are also more formalized fee-based support services, such as the *College Living Experience*, that partner with several academic universities, community colleges, and technical schools to provide wrap-around supports in the areas of academics, social skills, independent living, and career development.

There are other options for postsecondary education such as trade schools, which are typically 2 years or less, that focus on teaching hands-on skills. The Transition and Postsecondary Programs for Students with Intellectual Disability (TPSID) are model demonstration projects funded by the U.S. Department of Education that provide academic enrichment, socialization, independent living skills, and work training after high school exit. These programs are typically noncredit based. Resources such as *Think College*, also funded by the U.S. Department of Education, support evidence-based inclusive higher education options for individuals with IDD by generating and sharing knowledge; guiding institutional change; informing public policy; and engaging with students, professionals, and families (<https://thinkcollege.net/tpsid>). Data suggest that students with disabilities who spend most of their time in traditional classes and participating in campus culture have better postgraduation employment rates than those who spend most of their time in specialized classes (Grigal, Hart, Smith, & Papay, 2018).

To receive assistance or request accommodations for disability-related needs, a student must take the lead in disclosing his or her disability, providing current documentation of the disability and identifying needed accommodations. Thus, it is up to the student to independently navigate a new system of care and appropriately self-advocate for the accommodations that he or she needs. This requires that the student has a solid foundation in self-advocacy skills. The resource *Navigating College: A Handbook on Self-Advocacy* written for adults with autism provides an introduction to the college experience for students who are interested in postsecondary education (<http://autisticadvocacy.org/book/navigating-college/>).

Accommodations are established on a case-by-case basis and do not necessarily replicate those provided in the K–12 setting. Examples of accommodations that can be requested of DSS include extra time in test taking, a sign language interpreter, a note taker, and recorded books. Postsecondary education facilities that receive federal funding are required to provide reasonable accommodations to qualified individuals with disabilities under Section 504 of the Rehabilitation Act of 1973 (PL 93-112) and under Titles II and/or III of the ADA. HEOA was enacted in 2008, reauthorizing the Higher Education Act of 1965. This law improves access to postsecondary education for students with IDD by opening up eligibility for Pell grants, supplemental educational opportunity grants, and federal work-study programs and by creating TPSID model demonstration programs and coordinating centers for students with IDD (Smith, 2009).

Entering the Work Force

Work experience is a prerequisite for many jobs. Yet, only 58% of adults with ASD and 74% of adults with other IDD have ever worked between high school and their early 20s. Youth with ASD from ethnic minorities and low-income groups are further disproportionately affected by poor employment outcomes (Roux et al., 2015). Young adults with ASD have far higher rates of disconnection, meaning they never got a job or continued their education after high school, than their peers with other disabilities (Roux et al., 2015), while less than 8% of young adults with a learning disability, emotional disturbance, or speech-language impairment are disconnected, compared with 37% of those with ASD.

VR services should be accessed to facilitate transition-age youth with IDD entering the work force. Adults with ASD who received VR services have been found to have a strong chance of becoming employed once appropriate measures are in place (Jacob, Scott, Falkmer, & Falkmer, 2015). Similar findings have been described for adults with other IDD, with those receiving VR being 16 times more likely to be employed than those who don't receive these services. Employment rates in 2009 for the 15 million U.S. adults who have a disability were substantially lower than for adults who do not have a disability (16.8% versus 74%). In addition, poverty rates for adults who have a disability are substantially higher than those without disabilities (28.1% versus 10%; von Schrader, Erickson, & Lee, 2010). Even while participating in VR programs, transition-age adults with ASD across the country had yearly earnings below the poverty level for single adults during the 2002–2011 period, with overall mean wages increasing by only \$9 from the first to second half of the decade (Burgess & Cimera, 2014).

A plan for paid work experience should be written into a student's IEP starting no later than age 16 years (IDEA, 2004). Job placement choices should be based, when possible, on individual interests, abilities, and postsecondary goals. For example, if a student has set technology-related career goals, an appropriate placement would be one that allows the student to learn to apply these skills in a paid, community-inclusive work setting.

Work Options

Individuals with disabilities who are entering the work force, like those without disabilities, have the option of participating in full-time or part-time competitive employment (Butterworth, Smith, Hall, Migliore, & Winsor, 2009). Community-integrated employment became available for individuals with IDD in the 1980s

and rapidly became a preferred option to sheltered vocational workshops (a daytime activity for adults to perform routine tasks like assembly or manufacturing prior to gaining work in a community). However, some families still choose sheltered workshops because they provide consistent hours and long-term stability (Blick, Litz, Thornhill, & Goreczny, 2016). Another option is for the individual to attend an adult day care program that provides care and educational opportunities. While this option is better than spending time at home or in an institution (Campbell, 2012), most individuals with IDD and their families favor community-integrated employment over this and other daytime activities (Dague, 2012; Timmons, Hall, Bose, Wolfe, & Winsor, 2011). A recent study by Blick and colleagues (2016) demonstrated that individuals with IDD who were working in community-based settings reported increased choice and control over their daily activities and greater opportunities for community inclusion, as well as greater involvement in community activities, than adults in sheltered workshops and day care programs.

Competitive Employment An individual engaged in competitive employment is expected to perform essential functions at the same competence level as other employees without disabilities. Individuals with disabilities may request an accommodation under the protections of the ADA that enables them to perform these functions as long as the accommodation does not fundamentally alter the nature of the job. Accommodations covered by ADA include adaptive seating, computer input devices, large-print text, and so forth. To succeed in this **competitive employment** setting, individuals with disabilities must have the same skills requisite for any employee to succeed in the workplace. These skill sets include a knowledge base for the job, appropriate social skills, effective communication skills, and motivation. Individuals with disabilities also must have appropriate independent living skills and the ability to manage their disability-related needs, such as hiring and managing personal-care attendants and arranging transportation services.

Supported Employment **Supported employment** is defined by the Rehabilitation Act Amendments of 1986 (PL 99-506) and 1992 (PL 102-569) as employment in an inclusive setting with ongoing support services for an individual with a disability. Supported employment is a service that can help an individual gain competitive employment in inclusive work settings and provide ongoing support services to help maintain employment. Supported employment programs are

generally administered through the state-level Bureaus of Vocational Rehabilitation and state developmental disability agencies. These agencies help people with disabilities through the process of identifying and selecting a service provider who can then help the individual obtain employment by identifying supports through supervisor or coworker assistance (natural supports) or job coaches. A job coach or employment consultant is a person who is hired by the individual or the placement agency. His or her responsibility is to provide specialized on-site training that assists the employee with a disability in learning and performing his or her job and adjusting to the work environment, with the ultimate goal of full inclusion at the worksite (Degeneffe, 2000).

Customized Employment **Customized employment** is a position where a blend of services is provided to increase future employment options for individuals with significant disabilities. These may involve self-employment, entrepreneurship, job carving and restructuring (e.g., an existing job is adjusted so that it contains some, but not all, of the tasks from the original job description), or job sharing (e.g., when two or more people share the tasks of a job). In customized employment, the employer and employee work together to identify a role in the work setting, often creating a new position, to ensure that the employee is a fully integrated team member, that job expectations are in line with the individual's strengths and capabilities, and that the work environment and schedule optimizes success and productivity. The defining aspects of customized employment is the negotiated relationship and the fact that ongoing supports may or may not be necessary for success. Personal agents and customized training are often provided in this work setting (U.S. Department of Labor Office of Disability Employment Policy, 2009). The ideal implementation of customized employment practices replaces the traditional vocational evaluation with a discovery process for individuals with complex disabilities who may not do well in answering questions, completing assessments, and performing tasks that compares individuals to a normative sample. Rather than identifying the employment opportunity that meets the individual's skill sets and strengths with supported employment, customized employment uses a process of discovery, identifying the interests, skills, and abilities of the individual.

Work-Study Employment **Work-study employment** involves part-time work for students that is sanctioned by the school and occurs either on or off campus. Age-appropriate transition assessment information and the student's IEP goals for transition should inform

the appropriateness of this type of work. Internship experiences while in school improve employment outcomes (Carter, Austin, & Trainor, 2012; Wehman et al., 2014). Predictors of successful competitive postsecondary employment include paid employment for students while in the high school setting, providing students with direct and explicit instruction on vocational skills, ensuring that students graduate with a high school diploma, and supporting families in having high expectations for their son or daughter to be competitively employed (Southward & Kyzar, 2017).

Volunteering In today's competitive job market, **volunteering** is an opportunity for adolescents to gain valuable insights into the world of work, to develop skills, and to build work-related experience. It can be a positive step toward achievement of full employment or community inclusion goals in the IEP. However, volunteer experiences should not replace paid work experiences when those opportunities are also available, because paid work promotes the individual's self-esteem and pride in their abilities and lessens cultural stereotypes about the employability of individuals with developmental disabilities (Wolf-Branigin, Schuyler, & White, 2007).

Other Pework Options

Some youth with intellectual disabilities may not be ready to make the transition into a work-related setting immediately after exiting the school system (Targett, Wehman, West, Dillard, & Cifu, 2013). For these individuals, other more supportive options are available, such as day treatment/habilitation or work-readiness programs. These programs provide a more intensive level of support and focus on the development of daily living skills rather than job skills. The ultimate goal for any of these programs should remain moving the individual toward some aspect of employment.

MOVING FROM HOME INTO THE COMMUNITY

There are several key financial and legal issues that need to be addressed to ensure that at age 18, or when the individual is ready to move from home to the community, needed resources are available. This involves making sure that 1) there is no loss of income and/or services, 2) family assets are protected, and 3) youth with developmental disabilities are assured of having suitable independent living options. Financial barriers are the most common reason youth with developmental disabilities fail to make the transition to independent living in the community (McPherson et al., 2004).

Financial Options

Supplemental Security Income (SSI) is a monthly payment for individuals with disabilities. To qualify for SSI, individuals must meet both disability and financial eligibility requirements. SSI eligibility is generally determined using adult criteria when adolescents turn 18 years old, with the exception of youth enrolled in a Social Security Administration (SSA) work incentive program. Young people with developmental disabilities may lose their SSI at this time if they fail to meet the adult disability criteria. Conversely, some individuals with disabilities may now qualify for SSI when they had previously been ineligible because individual income, rather than household income, is now used to determine income eligibility. Generally speaking, adults who receive SSI cannot have individual assets greater than \$2,000. The SSA, however, does allow several important exceptions to this rule, which are referred to as work incentives (see <http://www.SSA.gov/work>).

Despite these incentive programs, a significant number of youth with developmental disabilities lose SSI benefits when they become adults. In 2009, adolescents in the 13–17 year age bracket represented 8.8% of SSI recipients. This dropped to 6.9% for young adults in the 18–21 year age bracket (Social Security Office of Retirement and Disability Policy, 2010). Youth who lose SSI benefits when eligibility is redetermined at age 18 should request a second review because more than one third of such requests result in the reinstatement of SSI benefits (American Academy of Pediatrics Council on Children with Disabilities, 2009; Rupp et al., 2005–2006). Some individuals who are found ineligible can continue to receive SSI benefits as long as they participate in approved VR programs. In most states, people who receive SSI automatically also qualify for Medicaid.

Social Security Disability Insurance (SSDI) provides a monthly payment for individuals with disabilities. There are two ways to qualify for SSDI benefits. Workers (including those in sheltered or supported work settings) who have paid into the Social Security system are eligible for SSDI if they are no longer able to work. Monthly SSDI benefits are also usually paid to an adult with developmental disabilities when a parent or guardian meets disability criteria and cannot work. If a parent who is entitled to SSDI benefits cannot work due to disability, retires, or dies and the child has qualifying disability determined prior to age 22, then the child is eligible for the benefits. It is important to know that beneficiaries who receive SSDI for more than 2 years are also eligible for health care coverage under Medicare.

Guardianship and Supported Decision Making

In most states, the natural **guardianship** of parents ends when children reach age 18. At that time, parents no longer have the legal authority to make decisions or sign consent forms for their child unless they submit an application for guardianship at their local probate court. Although every state has its own guardianship law, policy, and practice, the uniting principal across all states is that guardianship is a legal intervention and it is the decision of the court as to whether to appoint a guardian and who that guardian is going to be. The decision regarding the necessity of guardianship should be individualized, and guardianship is not always needed solely because a person has a particular diagnosis, disability, or IQ level. Two prerequisites must exist before a court appoints a guardian: 1) The person must show a lack of capacity (i.e., ability to make and communicate decisions) in important areas of life, such as health care or financial decisions, and 2) there must be a present need for the guardianship above and beyond other less restrictive options. In accord with the principles of self-determination, it is important to evaluate the extent to which an individual can participate in decisions that affect his or her own life (Buchanan & Brock, 1992; Burt, 1996). The National Resource Center for Supported Decision Making emphasizes that capacity can change based on experience, situation, or support needed. When exploring a person's capacity to make decisions, they encourage a careful examination of capacity through the following questions:

- What decisions need to be made?
- What is the person's history of making decisions?
- How has the person utilized help in the decision-making process previously?
- What services has the person enlisted to help with decision making?

Probate courts can appoint someone as a guardian over only that portion of a person's life where he or she shows incompetence and has a need (e.g., a health care guardianship or a conservatorship for finances). Making a decision about guardianship, well in advance of the 18th birthday if possible, is essential to the health transition process. When a youth who has a developmental disability cannot make health care decisions independently, there are several options to consider and procedures to follow in order to obtain legal guardianship. The process of establishing guardianship can be daunting for some families, but it can be necessary for helping caregivers continue to advocate more

effectively for their adult children if they need this level of support. Once obtained, guardianship papers should be kept in a wallet so that they can be presented at all health care encounters. Guardianship papers are as important as an insurance card when patients with developmental disabilities enter the adult health care system. The guardian is responsible for notifying relevant schools, agencies, and medical professionals of guardianship and may wish to have documents on file with these groups when appropriate. It is important to note that, ultimately, the decision for guardianship rests with the court. If the court disagrees with decisions made by the appointed guardian, they can take away the rights of that guardian and give it to someone else (National Resource Center for Supported Decision Making, 2016). As such, many families chose to explore other less restrictive options outside of the legal system that grant supported independence to their adult child.

There are several alternatives to guardianship that may be preferable because they increase the individual's autonomy to make decisions, avoid legal "red tape," and acknowledge the individual's needs and rights. In situations where legal guardianship is not indicated, support can be provided informally. Supported decision making is a model that allows individuals with IDD to retain their legal decision-making rights and is recognized as a viable alternative to guardianship. Supported decision making is defined as "practices, arrangements, and agreements that include informal and formal supports from diverse sources (e.g., peers, paid supporters, family, and technological supports, and educational supports" (Uyanik, Shogren, & Blanck, 2017, p. 499). Resources include the National Resource Center for Supported Decision Making (<http://supporteddecisionmaking.org>), the Center for Public Representation (<https://centerforpublicrep.org/initiative/supported-decision-making/>), and the Arc Center for Future Planning (<https://futureplanning.thearc.org>). In supported decision making, a **circle of support** or trusted group of supporters is created from family, friends, and/or community members to help answer questions and discuss options with the individual with IDD. The practices, arrangements, and agreements, however, are ultimately determined by the transitioning young adult (Uyanik et al., 2017; also see centerforpublicrep.org). This circle of support can help discuss the situation or decision to be made with the individual with IDD, provide insights or information about the situation, and help generate or compare options. In this capacity, supported decision making promotes self-determination, autonomy, and control. The individual being supported may wish to give a member of his or her team legal power of attorney to make legal decisions and take care of monetary issues on his or her

behalf. There is also the option of using a health care proxy, power of advocate, and Health Insurance Portability and Accountability Act (HIPAA) release as alternatives to legal guardianship. All these documents can be revoked by the individual at any time.

A variant of a circle of support is a **microboard** that is incorporated to include the individual with IDD as the chairperson (Wetherow & Wetherow, 2004). Although these sorts of informal alternatives to guardianship are considered best practice, it should be noted that a legal guardian or a **representative payee** is often required by programs and services, such as SSI and SSDI, in order to disburse funds to an individual with IDD. The paperwork for this should be completed before age 18 to avoid interruption in benefits.

Housing

Finding and securing housing and residential supports for adults with IDD can be challenging for the individual and the family. In one study, 28% of adults with developmental disabilities were found to live in their own home, 58% lived with their families, and 15% resided in publicly funded residential settings (Larson et al., 2011). Most new group homes are designed for one to three individuals and are often referred to as **independent residential alternatives** (IRAs), reflecting a trend away from institutional settings of 16 or more people, which was the norm a generation ago. In 2009, the average per-resident expenditures per year were \$203,670 in state-operated IRAs (Larson et al., 2011). Home- and community-based services and programs for young adults with developmental disabilities cost substantially less and are in high demand. However, waiting lists are the norm. Over 100,000 individuals with IDD in the United States were waiting for residential services in 2009 (Larson et al., 2011).

Services and programs that assist individuals with community living have increased dramatically since the 1990s as a result of the New Freedom Initiative (Executive Order No. 13217, 2001), the ADA, and the Olmstead decision (*Olmstead v. L.C.*, 527 U.S. 581, 1999). The Olmstead decision interpreted Title II of the ADA to require states to administer their services, programs, and activities "in the most integrated setting appropriate to the needs of qualified individuals with disabilities" (*Olmstead v. L.C.*, 1999). The act holds that states are responsible for integration of individuals with IDD into the community optimizing inclusion in everyday life activities, family relations, and social contacts.

Family Home Many families whose adults have IDD choose for the individual to continue to live at

home. Between 1999 and 2009, the number of adults with developmental disabilities living with family members in the United States increased by two thirds, from 355,152 to 599,152 (Larson et al., 2010). The aging of these families, however, is an emerging concern. Approximately one quarter of home-based adults with developmental disabilities live in homes headed by elderly parents, and support systems for aging parents of adults with developmental disabilities are lacking (Heller, Caldwell, & Factor, 2007).

Group Homes The life expectancy for individuals with IDD are comparable to the general population; therefore, demand for residential services is on the rise. The number of people with ID receiving residential services grew from 267,682 in 1988 (Lakin, Prouty, Polister, & Coucouvanis, 2003) to 460,597 in 2011 (Larson, Salmi, Smith, Anderson, & Hewitt, 2013). Stemming from landmark legislation in the 1960s (Community Mental Health Act; PL 88-164) and 1980s (Omnibus Budget Reconciliation Act; PL 100-203) and the Olmstead Act, the number of individuals with ID living in state institutions and nursing homes has steadily declined. Concurrently, there has been a rapid growth in the number of small residential settings. The most common form of assisted-living program (outside of the family home) is the group home (Lakin et al., 2010), most of which have on-site counselors who provide supervision and support in daily living skills, employment, and recreation.

Supported Living Services Supported living services (SLSs) provide assistance to adults with developmental disabilities who live in homes in the community that they own or lease. SLSs may include assistance with 1) selecting and moving into a home, 2) choosing personal attendants and housemates, 3) acquiring household furnishings, 4) addressing common daily living activities and emergencies, 5) becoming a participating member in community life, and 6) managing personal financial affairs (Stancliffe & Lakin, 2005).

MOVING FROM PEDIATRIC- TO ADULT-ORIENTED HEALTH CARE

Historically, addressing the health care needs of young adults with IDD mostly fell in the court of pediatrics, as most internists and family practitioners do not receive formal training caring for adults with IDD and are uncomfortable in these settings (Peter, Forke, Ginsburg, & Schwarz, 2009). As the need has grown to provide these services, the health care system has responded by developing resources for adult medical care providers

to prepare them to accept adults with IDD into their practices. More education in medical school and graduate medical education programs should focus on meeting the needs of this vulnerable population.

The importance of young adults having a medical home cannot be overemphasized (see Chapter 41; see also Box 40.2). Many practice-based resources are available from the National Health Care Transition Center (<http://www.gottransition.org/>) and include toolkits for health care providers, parents and families, and the youth with special health care needs. Specific strategies for the successful transition to an adult medical home model are outlined in the joint statement on health care transition put forth in 2011 (American Academy of Pediatrics et al., 2011). In addition, the American College of Physicians developed a toolkit for internal medicine practices that accept youth with special health care needs, including a specific package for youth with IDD available at www.acp.org. Family medicine practices are also well equipped to provide a medical home throughout the life course of individuals with IDD.

Role of Families

Transition planning should consider the needs of the entire family (<http://www.p2pusa.org>; Taylor, Hodapp,

Burke, Waitz-Kudla, & Rabideau, 2017) and include parent training to advocate for youth with IDD (Cheak-Zamora, Teti, Maurer-Batjer, & Koegler, 2017). Improved communication and support for developing self-efficacy are often needed as parents advocate for postsecondary independence while continuing to be primary caregivers. Often this time of transition leads to high levels of stress and anxiety for the caregiver(s) and can adversely impact their own physical and mental health (Betz, Nehring, & Lobo, 2015).

An algorithm for transitioning youths with developmental disabilities to adult health care is outlined in a recent clinical report (American Academy of Pediatrics et al., 2011) that underscores the importance of the patient-centered medical home that provides comprehensive primary care and facilitates partnerships among the individual patient, health care provider, and families (American Academy of Family Physicians et al., 2007). The transition algorithm is driven by a process that includes a longitudinal assessment of readiness, planning, implementation, and documentation of specific transition goals. This algorithm identifies a sequence of four steps of transition-related activities that are ideally, although not necessarily, implemented at specific ages:

Step 1: Discuss the transition policy of the pediatric practice—that is, when the child should transition to adult care (12–13 years of age)

BOX 40.2 EVIDENCE-BASED PRACTICE

Transition from Pediatric to Adult Care

Incomplete transition from pediatric to adult care has been associated with many negative outcomes, including lack of a primary care medical home, foregone care, poor medical outcomes, increased mortality, and difficulty accessing care in a crisis (Acharya, Meza, & Msall, 2017; Lotstein et al., 2013; Tanner et al., 2016). Youth with developmental disabilities are at high risk for not receiving appropriate anticipatory guidance and support around transition planning, and they often require parental/guardian support to navigate the complex adult-oriented health system (McKenzie, Sanders, Bhattacharya, & Bundorf, 2018). Youth of color and non-English speakers are more at risk for being unprepared for health care transition.

There is evidence that adolescent and young adults with increased medical needs who receive specialized hospital-based care coordination during health care transition have improved perception of quality of chronic illness care and reduction in cost and health care utilization (Lemke et al., 2018; Simon et al., 2017). Parental involvement is important to adherence but must be balanced with the need to transfer responsibilities for disease management to the youth. Families remain integral supports for many adults with IDD, but families must learn to balance their advocacy role with their role in supporting the youth's development of self-advocacy skills.

Points to Remember

- Gaps in health care can result in poor health outcomes.
- Evidence supports implementing a structured systematic transition process for improved outcomes.
- Parent involvement is important and necessary but should be balanced with supporting their child's development of self-advocacy skills.

Step 2: Initiate a transition plan jointly with parent and youth (14–15 years of age)

Step 3: Review and update the transition plan (16–17 years of age)

Step 4: Transfer care to adult provider(s) (18–21 years of age)

Written documentation is a key element of the actual transfer of care. It is recommended that adult providers be given a copy of the transition plan as well as documentation of a youth's transition readiness (i.e., self-care and health care navigation skills). They should also be provided with legal documentation (including a signed HIPAA form, a health care proxy, power of attorney, and power of advocate and/or guardianship paperwork) that clearly defines the responsible party for medical decision making. Finally, adult providers should be given a portable medical summary that includes a succinct medical history as well as 1) a list of medical providers; 2) key social service providers; 3) baseline functional and neurologic status; 4) cognitive status, including formal neuropsychological test results and date of administration; 5) condition-specific emergency treatment plans and contacts; and 6) the patient's health education history. The summary should also include an assessment of the individuals' understanding regarding his or her health conditions, treatments, and prognosis. There should be particular attention focused on entry into adult life, including sexuality, family planning, and relevant genetic information. **Medication reconciliation** (where the medication lists are checked for accuracy and to make sure there are no adverse interactions) is recommended at both the giving and receiving end of the transfer from child to adult health care provider. To achieve an effective transfer of care, it is important that there be direct communication between the pediatric and adult providers (The Society for Adolescent Health and Medicine, 2017).

Adherence and Health Literacy

In order to be ready to move into the adult health care system, the adolescent needs 1) to be responsible for taking medications (with supervision when appropriate), 2) to understand and be able to discuss his or her disability, and 3) to use required adaptive equipment or appliances (American Academy of Pediatrics et al., 2011; The Society for Adolescent Health and Medicine, 2017). During the transition process, health care professionals should consider when to start seeing the individual alone (without parents) and when to develop a confidential relationship with the patient.

Health Promotion

Good nutrition, regular exercise, and fostering personal relationships are key parts of maintaining health and quality of life, yet youth with IDD 9–18 years of age spend more time in sedentary activities than their peers and are less fit (Tyler, MacDonald, & Menear, 2014). This problem is amplified when medication that increases appetite and weight gain (e.g., risperdal and olanzapine) is used to manage mood or disruptive behaviors in this population. Early and sustained participation in community-based programs is essential for adolescents and young adults to maintain healthy lifestyles beyond the school years. Lack of physical activity can lead to obesity-related disorders (e.g., type 2 diabetes), which disproportionately affect people with disabilities (Rimmer, 2017).

Leisure activities are very important for young adults with developmental disabilities, as these individuals tend to become socially isolated. People with developmental disabilities requiring extensive to pervasive support (i.e., those with severe to profound intellectual disability) are less likely to participate in leisure activities (Van Naarden Braun, Yeargin-Allsopp, & Lollar, 2009). Therapeutic recreation programs that incorporate social skills training can help individuals with mild-moderate intellectual disability hone their conversation skills, learn to maintain eye contact and use appropriate body language, and become self-advocates (<https://www.atra-online.com/page/AboutRecTherapy>). Examples of therapeutic recreation programs include the Special Olympics (<http://www.specialolympics.org/>) and Best Buddies programs (<http://www.bestbuddies.org/>). For individuals with motor impairments, there is Wheelchair and Ambulatory Sports USA (<http://www.wsusa.org/>). The National Center on Physical Activity and Disability (<http://www.ncpad.org>) is a clearinghouse for information promoting physical activity among individuals with disabilities.

Engaging in personal relationships is also a key part of development for all youth. Opportunities for friendships may need to be facilitated, especially once youth are no longer enrolled in school. Companionship, emotional support, and increased self-esteem are all benefits of personal relationships that can increase quality of life.

Sexuality

Sexuality and the formation of romantic relationships are natural aspects of human development and are important for all young adults regardless of gender, orientation, or cognitive level (Ailey, Marks, Crisp, & Hahn, 2003; Pecora, Mesibov, & Stokes, 2016). Many individuals

with IDD have the same level of sexual interest as their typically developing peers (Byers, Nichols, & Voyer, 2013; Dewinter, De Graaf, & Begeer, 2017). Youth with IDD can reach biological sexual maturity on a developmental trajectory similar to their typically developing peers, but may lack insight into the socioemotional processes that accompany this development and interest. Core social-communication deficits create a unique burden on these individuals related to sexuality, dating, and friendships and can increase the risk of exploitation due to the difficulty in their recognizing dangerous situations (Brown-Lavoie, Viecili, & Weiss, 2014).

Unfortunately, adolescents with developmental disabilities often do not receive adequate information about sexuality and reproductive health (i.e., sexually transmitted infections, contraception, and reproduction; Brown-Lavoie et al., 2014; Hannah & Stagg, 2016). This places the individual at increased risk to experience sexual victimization and exploitation (Brown-Lavoie et al., 2014). As one example, females with ASD have been found to be at an increased risk for unwanted sexual interactions and adverse sexual experiences compared with their typically developing peers (Pecora et al., 2016). Issues around boundaries, normative sexual feelings, masturbation, relationships, intimacy, and privacy should be addressed early for all youth with IDD. Woodbine Press has a number of excellent books for youth and parents with IDD that discuss puberty, sexuality, and relationships, and *Supporting Teens with Autism on Relationships (STAR)* is a free self-guided skill-building resource that adapts empirically based sexuality education approaches and interventions for parents of children and teens ages 10–18 who have an ASD (http://www.danya.com/autism_pdfs/STAR%20Charting%20the%20Course%20Parent%20Guide.pdf).

In addition, many youth require significant support around puberty and menses, which can be distressing to many girls with IDD. During pubertal development, typical physical and emotional changes can be difficult for youth with IDD to understand and navigate. For example, approaches to dealing with wearing a bra or sanitary pad, unreciprocated romantic feelings, desire for parenthood, and dating often need parent facilitation. Sexuality is more than sex; it is how a youth feels about his or her developing body.

Another important area of sexuality education is around gender variance. Data suggest that gender variance and varied sexual attraction are more common in adolescents and young adults with developmental disabilities, especially ASD, than in the typically developing population (Van Schalkwyk, Klingensmith, & Volkmar, 2015). One study found that parents of youth with ASD without ID were over seven times more likely to report that their child expressed gender

variance than typically developing children and that this occurred equally in females and males (Strang et al., 2016).

Moreover, women with ASD have reported lower rates of heterosexual preference, higher rates of bisexual attraction, and more uncertainty in their attraction toward specific sexes compared with typically developing peers (May et al., 2017). It often can be difficult to define gender dysphoria and transgender identity in individuals with IDD due to social, cognitive, and adaptive limitations. In addition, the gender they identify with may not always match the way they physically present themselves to others. Therefore, parents, health care providers and teachers should pay attention to the development of gender identity at an early age, as gender dysphoria can contribute to fewer meaningful social interactions, significant emotional distress, and poor school performance. The focus should be on acceptance and providing the opportunity for individual exploration of gender-related concerns.

Professionals and parents may either lack the awareness to consider sexuality as part of the adolescent's typical growth and development or are fearful of discussing sensitive issues and acknowledging vulnerability (Murphy, 2005; Tice & Hall, 2008). This results in an information gap that may increase the chances of sexual exploitation and unintended pregnancy. For example, youth with developmental disabilities are four times more likely to be sexually abused or exploited than their typically developing peers (Bowman, Scotti, & Morris, 2010; Dixon, Bergstrom, Smith, & Tarbox, 2010). Lack of knowledge of sexuality, lack of information on exploitation, cognitive deficits, poor social skills, poor self-esteem, and poor body image are some of the factors that place adolescents with developmental disabilities at increased risk (Bowman et al., 2010; Dixon et al., 2010).

Mental Health

Individuals with IDD are also at a higher risk for developing mental health problems than their typically developing peers (see Chapter 27). This so-called “dual diagnosis” affects nearly 40% of children with ID compared with 8% in the general population (Emerson, 2003). While these issues often begin in childhood, they are likely to persist into adulthood and interfere with adaptive functioning (Sukhodolsky, Block, Panza, & Reichow, 2013). Psychosis and behavior disorders, including aggression toward others and self-aggression, are higher than in the general population. The rate for substance abuse, however, is lower than in the general population (Deb, Thomas, & Bright, 2001; Slayter, 2010). The proportion of anxiety and mood disorders are similar to the

general population except for in ASD, where 40%–85% of individuals have specific phobias, generalized anxiety, social anxiety, and separation anxiety. This also is true for depression, sleep disorders, seizures, gastrointestinal issues, and multiple other medical and mental health conditions. In addition, individuals from diverse racial and cultural groups may disproportionately miss out on ASD diagnoses and have other labels instead (Bishop-Fitzpatrick & Kind, 2017).

In contrast to ASD, cerebral palsy has not been reported as having increased rates of psychiatric diagnosis, although ascertainment may be problematic. In general, boys and teens with IDD have higher rates of dual diagnosis than girls and younger children. Factors associated with an increased risk of psychopathology include, in addition to age and gender, social deprivation, family composition, number of potentially stressful life events, mental health of the child's caregiver, and family functioning (Emerson, 2003).

However, despite the high reported rates of dual diagnosis, the proper diagnosis of mental illness in a person with IDD remains a challenge. Reiss, Levitan, and Szyszko (1982) termed one major obstacle *diagnostic overshadowing*. This refers to the tendency of clinicians to attribute all the behavioral and emotional problems to the developmental disability itself rather than to a comorbid mental illness. Another problem is that many professionals in the field of mental illness simply do not have training or experience in the field of developmental disabilities (Fletcher, Loschen, Stavrakaki, & First, 2007).

Most service systems for people with developmental disabilities are oriented to chronic care and long-term support, and they provide limited, if any, services for acute mental health crises. Emergency mental health services are typically geared to the needs of the general population. Access to preventive mental health services is problematic as well. Adults with developmental disabilities are seven times more likely to report inadequate emotional support, compared with adults who do not have disabilities (Havercamp, Scandlin, & Roth, 2004).

Behavioral concerns should be investigated rather than ascribed to the individual's developmental disability. It is important to question adolescents and their families about physical symptoms of anxiety and depression, such as altered sleep patterns and appetite. Professionals and educators should also monitor excessive school absences as these may be evidence of a mental health issue.

Studies have also shown a significantly increased prevalence of eating disorders in patients with ASD as compared with healthy control patients (Huke, Turk, Saeidi, Kent, & Morgan, 2013). A restricted food repertoire is common in youth with ASD and can stem from

sensory aversions to taste or texture or to cognitive rigidity in trying new or different foods. Screening for disordered eating and referral to a mental health provider and/or nutritionist should be considered for all youth with avoidant or restrictive food intake.

Environmental factors should be considered as precipitants when adolescents with IDD present with new challenging behaviors. For example, it is not unusual for an adolescent with developmental disabilities to experience anxiety when a long-term aide is no longer available at school or when opportunities to socialize diminish with high school graduation. Surgery, a prolonged hospitalization, or medical setbacks can precipitate depressive episodes. It should be emphasized that challenging behaviors occurring across all settings (as opposed to being generated in response to a specific stimulating event or situation) are more likely to be due to organic causes than when they occur in the typical population. Treatments can include psychological, behavioral, pharmacotherapy, and/or environmental interventions. Community-based models of support combined with neuropsychiatric intervention can be a potent therapeutic approach in the management of challenging behaviors in individuals with developmental disabilities (Ferrell, Wolinsky, Kauffman, Flashman, & McAllister, 2004).

SUMMARY

- Health care providers, educators, other professionals, and families should foster the expectation that youth and young adults with IDD will become healthy, happy, active, and productive members of their community.
- Youth with IDD should be provided with opportunities to learn about their strengths, abilities, skills, needs, and interests.
- Youth with IDD should assume responsibility for themselves and understand the difference between the protected worlds of school and home and the worlds of work and adult life. Most of all, they must believe they are capable of success.
- These goals can be accomplished through comprehensive transition planning and advocacy, including self-advocacy, to promote full participation in society.

CHAPTER 41

Medical Home and Health Care Systems

Renee M. Turchi and Angelo P. Giardino

Upon completion of this chapter, the reader will

- Define the terms *children and youth with special health care needs* and *children with medical complexity* and understand the impact of these diagnoses on health care delivery and financing issues
- Describe the complexity involved in developing a medical home that adequately coordinates various services, integration of care, teams, and the risk adjustment for this population
- Discuss trends in alternative payment models and insurance coverage in the provision of health care to these children
- Describe how public health care programs and benefits contribute to these children and their families in achieving patient and family centered care

The federal Maternal and Child Health Bureau (MCHB) defines children and youth with special health care needs (CYSHCN) as “those who have or are at increased risk for a chronic physical, developmental, behavioral or emotional condition and who also require health and related services of a type or amount beyond that required by children generally” (McPherson et al., 1998 p. 138). Based on this definition (Bethell et al., 2015), the National Survey of Children’s Health (2016) found an overall national prevalence of 19% of CYSHCN. This is a significant increase from the 2005–2006 estimate of 14% (U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau, 2007) and 2010 estimate of 15% (U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau, 2013). One in five

U.S. households with children includes at least one CYSHCN (U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau, 2014). The 2009–10 National Survey of Children with Special Health Care Needs (U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau, 2013), confirmed that CYSHCN is a diverse group comprised of all races, ethnicities, ages, family incomes, and levels of functional abilities.

Children with medical complexity (CMC) are a subset of CYSHCN; they have multiple chronic conditions often requiring the care of an array of community- and hospital-based providers (Cohen et al., 2011). While CMC have an estimated prevalence of only 0.5%, or 400,000 in the United States (Kuo, Cohen, Agrawal,

Berry, & Casey, 2011), their care accounts for almost one third of annual health care expenditures for children, totaling nearly 100 billion dollars (Cohen et al., 2012; Lassman, Hartman, Washington, Andrews, & Catlin, 2014). CMC have chronic severe health conditions, increased needs for services, major functional limitations, and high health care utilization (Berry et al., 2013).

The term CYSHCN therefore includes an overlapping subgroup of children with developmental disabilities (e.g., cerebral palsy and meningomyelocele), a group of CMC, and a group of typically developing children with complex medical problems (e.g., hemophilia, diabetes, and severe asthma; Davis & Brosco, 2007). Understanding the similarities and differences among the groups can inform clinical decision making, policy development, and resource allocation. (Neff et al., 2014). The need to develop clear definitions of CYSHCN and CMC has fostered research investigating prevalence, quality of care, and health outcomes for this population. However, each group shares similarities around health care structures, processes, policies, and outcomes. Further, there is a cohort of children who fall into multiple groups, as they have both a developmental disability and complex medical problems. Defining this population in pediatric systems is important to deliver effective care across settings in both medical (inpatient/outpatient) and community sectors to best meet the needs of families, to measure outcomes, and to address costs and utilization (Cohen et al., 2018).

It is important to distinguish CMC as a subset of CYSHCN, as cost of care for CMC accounts for nearly one third of all health care spending on children, with high emergency department utilization, hospitalizations, and readmissions (Berry, Toomey, et al., 2013; Neuman et al., 2014). In fact, readmission to the hospital for this population is equivalent to or exceeds that of the elderly (Berry, Hall, et al., 2014; Berry, Toomey, et al., 2013; Cohen et al., 2012).

Thought Questions:

Discuss the role of a medical home for CYSHCN and CMC and how it might impact their overall quality of life. Describe opportunities and challenges in a value-based payment system for CSHCN/CMC. What issues makes financing care for CYSHCN and CMC unique from the perspectives of health care provider, insurer, parent/caregiver, and hospital systems? Examine the various evidence-based models of financing a payment model for CYSHCN.

HEALTH CARE UTILIZATION

Developing an effective health care system that includes a medical home for CYSHCN is the focus of this chapter. The optimal functioning of a high-performing, quality medical home and care coordination system is essential for CYSHCN given the complex array of services required to maintain and improve their functioning. Several of the core features of this system are important for all children (Stille et al., 2010), yet CYSHCN may require an array of services beyond the primary care doctor, including those provided by specialists, therapists, pharmacists, educators, mental health providers, home health care providers, medical equipment providers, and community partners (American Academy of Pediatrics, 2014). Families and clinicians need to invest significant time and effort in coordinating and communicating among providers and across organizations/systems, ensuring that recommendations, financial, insurance, and necessary services are in the care plan (Kuo et al., 2011). Table 41.1a lists a comparison of health care expenditures and utilization between CYSHCN and their peers without disabilities. Table 41.1b lists specific health services utilized by the CYSHCN represented in the 2009–2010 NS-CYSHCN (U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau, 2013).

To place the utilization of health care services for CYSHCN and CMC in context, Bui and colleagues (2017) examined data from 1996 to 2013. Their study showed that health care spending on all children in the United States increased from \$150 billion to \$234 billion in that 17-year period (using inflation-adjusted 2015 dollars). The \$234 billion accounted for 8.4% of total health care expenditures in 2013 and accounted for 1.42% of the gross domestic product, resulting in a cost of \$2,788 per child in the United States that year. The top 10 condition categories and their associated costs were the following:

- Well newborn care in the hospital setting (\$27.9 billion)
- Attention-deficit/hyperactivity disorder treatment (\$20.6 billion)
- Well dental care, including dental check-ups and orthodontic care (\$18.2 billion)
- Asthma care (\$9 billion)
- Treatment of oral disorders, including caries, extractions, and oral surgery (\$8.7 billion)
- Well child care in the ambulatory setting (\$8.5 billion)

Table 41.1a. Comparison of health care expenditures and utilization between children and youth with special health care needs (CYSHCN) and children without disabilities

Category	CYSHCN	Children without disabilities	Comparison
Hospital days	552 days/1,000	90 days/1,000	6 times higher
Physician visits	4.6 visits/year	1.9 visits/year	2 times more visits
Nonphysician professional visits	3 visits/year	0.6 visits/year	5 times more visits
Prescriptions	6.94 medications/year	1.22 medications/year	5 times the number of prescriptions
Home health provider days	1.73 days/year	0.002 days/year	865 times more days
Health care expenditures	\$2,335/year	\$652/year	3 times the cost
Out-of-pocket expenditures	\$352/year	\$175/year	2 times the cost

Sources: Agency for Healthcare Research and Quality (2003); Newacheck, Inkelas, and Kim (2004); and Newacheck and Kim (2005).

Table 41.1b. Health care utilization for children and youth with special health care needs (CSHCN) identified in the 2009–2010 National Survey of Children with Special Health Care Needs

Sample: The presence of a condition expected to last at least 1 year and at least one of the following:

1. The use of or need for prescription medication
2. The use of or need for more medical care, mental health services, or education services than other children of the same age
3. An ongoing emotional, behavioral, or developmental problem that requires treatment or counseling
4. A limitation in the child's ability to do the things that most children of the same age do
5. The use of or need for special therapy, such as physical, occupational, or speech therapy

Description: The need for prescription medication is the most highly utilized service (76% of CYSHCN); followed by the use of or need for extra medical, mental health, or educational services (42.1%); followed by the need for or use of services for ongoing emotional, behavioral, or developmental (EBD) problems (31.8%), limitation in activities (23.5%), and the use of specialized therapies (21.5%). The percentages do not add up to 100 because each child may experience more than one consequence of his or her condition(s).

From U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau. (2013). Consequences of special needs. In *The National Survey of Children with Special Health Care Needs chartbook 2009–2010*. Rockville, MD: Author. Retrieved from <https://mchb.hrsa.gov/cshcn0910/population/pages/hfs/csn.html>

- Treatment of upper respiratory infections (\$8.4 billion)
- Care for long-term respiratory conditions, such as sleep apnea, allergic rhinitis, and chronic sinusitis (\$8.1 billion)
- Treatment of dermatologic conditions, such as cellulitis, cysts, acne, and eczema (\$8 billion)
- Emergency treatment of mechanical forces, such as striking an object and cuts (\$7.8 billion)

Kogan, Strickland, and Newacheck (2009) estimated that in the first decade of the 21st century, at least 1 in 7 or about 10 million children in the United States had an existing special health care need and had expenditures about three times higher than typically developing children, accounting for 42% of the health care costs spent on child health care (see Tables 41.1a and 41.1b).

Newacheck and Kim (2005) estimated that, on average, out-of-pocket expenses for CYSHCN are about twice what they are for typically developing children. Specifically, of the total cost of services, the following percentages are paid out of pocket by families of CYSHCN:

- 12% of nonphysician services such as physical and occupational therapy
- 14% of physician services
- 30% of prescription costs
- 40% of related services, including vision aids, medical supplies, and other equipment
- 67% of dental services

At least a quarter of families with a CYSHCN and CMC spend at least \$1,000 out of pocket per year on expenses related to the CYSHCN/CMC. It should be noted that for lower income families, expenditures of \$250 or more are associated with a family perception of a financial burden (Lindley & Mark, 2010). In addition, lower income families experience greater financial burden than those with higher incomes (Newacheck et al., 2004).

An Institute of Medicine report (2001) suggested that the fragmentation of health care in the United States jeopardizes quality of care. To address this concern, all children, whether with a disability or typically developing, should be provided comprehensive health care that is coordinated and occurs within a *medical home* framework and includes care coordination with integration across systems (American Academy of

Figure 41.1. The IHI Triple Aim/Quadruple Aim. (Adapted with permission from the Institute for Health Care Improvement [www.ihc.org] and Bodenheimer [2014].)

Pediatrics, 2014). However, optimizing care coordination and family engagement through the medical home model requires an integrated assessment, and this should be consistent with the Institute for Healthcare Improvement's Triple Aim framework that focuses on patient outcomes (i.e., population health), patient/family experience, and per-capita costs (Berwick, Nolan, & Whittington, 2008). More recently, Bodenheimer and Sinsky (2014) proposed expansion of the Triple Aim to a Quadruple Aim, adding provider satisfaction and well-being as an essential component of the framework (see Figure 41.1).

THE CONCEPT OF THE MEDICAL HOME

The concept of a medical home is not new; it was proposed over 50 years ago by the American Academy of Pediatrics (1967) to help families with care coordination and to improve care. Thirty-five years later, the American Academy of Pediatrics (2002) expanded the statement to include a more comprehensive interpretation of the concept along with operational definitions that would make it easier to recognize care as being consistent with medical home principles. They called for all children to have "a medical home that provides accessible, continuous, comprehensive, family-centered, coordinated, and compassionate health care in an atmosphere of mutual responsibility and trust among clinician, child, and caregiver(s)" (American Academy of Pediatrics, 2002, p. 185). Then, in 2007, the adult and pediatric primary care organizations agreed on core principles, referring to this care model as the patient-centered medical home (American Academy of Family Physicians, 2010). The American Academy of Pediatrics' National Center for Medical Home Implementation (2017) references the medical home policy statement (American Academy of Pediatrics, 2002) in describing

the medical home as an approach to providing comprehensive and high-quality primary care. The authors state that the important characteristics of a patient- and family-centered medical home are the following:

- **Accessible:** Care is easy for the child and family to obtain, including geographic access and insurance accommodation.
- **Family centered:** The family is recognized and acknowledged as the primary caregiver and support for the child, ensuring that all medical decisions are made in true partnership with the family.
- **Continuous:** The same primary care clinician cares for the child from infancy through young adulthood (18–21 years), providing assistance and support for transition to adult care.
- **Comprehensive:** Preventive, primary, and specialty care are provided to the child and family.
- **Coordinated:** A care plan is created in partnership with the family and communicated to all health care clinicians and necessary community agencies and organizations.
- **Compassionate:** Genuine concern for the well-being of the child and family are emphasized and addressed.
- **Culturally effective:** The family and child's culture, language, beliefs, and traditions are recognized, valued, and respected.

Notably, a medical home is **not** a building or place—it extends beyond the walls of a clinical practice. Ideally, a medical home builds partnerships with clinical specialists, families, and community resources, and it recognizes the patient's family as the constant in the child's and adolescent's life (National Center for Medical Home Implementation, 2017). This partnership is paramount for children with disabilities, as they require multiple services and systems to maximize their functioning and outcomes.

Health disparities exist regarding access to quality medical homes for CYSHCN among racial and ethnic minorities (Guerrero, Zhou, & Chung, 2018). Addressing issues of cultural and linguistic competency among CYSHCN is essential for practices and programs that provide services and develop policies for CYSHCN (Telfair, Bronheim, & Harrison, 2009). The issue of health care disparities is further discussed in Chapter 42.

Effective primary care has long been recognized as a valuable component for all children in the highly

specialized, technology-dependent, tertiary care-based health care delivery system in the United States. Starfield (1992) defined primary care as health care that is 1) first contact, involving an initial physician to whom the family goes to for routine and nonroutine care; 2) community based and accessible; and 3) longitudinal (continuous), coordinated, and comprehensive. In addition, primary care clinicians for children (e.g., community pediatricians, family physicians, and nurse practitioners) provide preventive care, including well-child examinations; immunizations; and vision, hearing, developmental and medical screenings. Primary care also includes personalized care that demonstrates the clinician's knowledge of the patient and family environment, including work, personal, emotional, and—at times—financial concerns. For the child and family, often the primary care team's medical home coordinates care with the pediatric subspecialist(s), the school system, and community providers to ensure comprehensive care. In a few instances, the subspecialist assumes the majority of the responsibilities for the medical home. In some unusual cases, the specialist may also provide well-child care (e.g., for a child with cystic fibrosis who is receiving care at a comprehensive center run by a pulmonologist).

The most recent National Survey of Children's Health (2016) (sponsored and designed by the MCHB at the Health Resources and Services Administration in partnership with the National Center for Health Statistics at the Centers for Disease Control, Child and Adolescent Health Measurement Initiative, and a national technical expert panel) characterizes and describes many aspects of the medical home and systems issues for CYSHCN. The survey demonstrates that the overall prevalence of children with disabilities has increased over time. Figure 41.2 shows how the prevalence of selected developmental disabilities has increased from 2014 to 2016 as well as the overall prevalence of developmental disabilities.

The Patient-Centered Primary Care Collaborative (2017) has examined the effectiveness of both child and adult health care settings based on peer-reviewed literature. They have identified a growing body of literature demonstrating a positive effect of care delivery provided by a patient- and family-centered medical home on cost, quality, and utilization (see Figure 41.3). The results are not unanimous, but the analysis shows that the longer a practice has been operating as a patient- and family-centered medical home and the higher the medical complexity of the patient population being cared for, the more significant positive effects are measured, especially in the cost-savings realm.

Prevalence (percentage) of children ages 3–17 years ever diagnosed with selected developmental disabilities, by year: United States, 2014–2016

Selected developmental disability measure	Estimate (95% confidence interval ¹)	Standard error
Autism spectrum disorder		
2014	2.24 (1.90–2.63)	0.18
2015	2.41 (2.01–2.85)	0.21
2016	2.76 (2.29–3.29)	0.25
Intellectual disability		
2014	1.10 (0.89–1.37)	0.12
2015	1.34 (1.03–1.71)	0.17
2016	1.14 (0.87–1.47)	0.15
Other developmental delay		
2014	3.57 (3.11–4.07)	0.24
2015	3.56 (3.07–4.10)	0.26
2016	4.55 (4.00–5.15)	0.29
Developmental disability		
2014	5.76 (5.20–6.37)	0.29
2015	6.04 (5.39–6.75)	0.34
2016	6.99 (6.28–7.76)	0.37

¹95% confidence interval was calculated using the Korn-Graubard method for complex surveys.

Figure 41.2. Estimated prevalence of children ages 3–7 diagnosed with developmental disabilities in the United States 2014–2016. Note: The linear increase from 2014–2016 is statistically significant ($p < 0.05$). (Source: National Center for Health Statistics, 2018.)

THE IMPORTANCE OF COORDINATION OF CARE

Given the many services that may be needed and the number of providers and professionals potentially involved in coordinating the various health care services required by CYSHCN and CMC, coordinating care is important for both the child and family and the health care providers. The child's needs may be complex, and a great deal of time, energy, and skill are required to ensure that the different agencies, institutions, and professionals work effectively together in developing a comprehensive plan of care (American Academy of Pediatrics, 1998, 2014). Effective care coordination and integration are defined as “the set of activities ‘in the space between’ visits, providers and hospital stays.” (American Academy of Pediatrics, 2014, p. e1452.). Integrated care provides effective health care services, from the perspective of the patient and family, across the entire care continuum (American Academy of Pediatrics, 2014). This is particularly relevant

Summary of outcomes: Peer-reviewed articles

ED utilization (n=10)

PCP utilization (n=7)

Figure 41.3. The impact patient and family centered medical home has on cost, quality, and utilization. Summary of outcomes: Peer-reviewed articles (From Jabbarpour, Y., De Marchis, E., Bazemore, A., & Grundy, P. [2016.] Impact of Primary Care Practice Transformation on Cost, Quality, and Utilization: A Systematic Review of Research. Executive Summary. Patient-Centered Primary Care Collaborative. Robert Graham Center. P 5. https://www.pcpcc.org/sites/default/files/resources/pcmh_evidence_es_071417%20FINAL.pdf; reprinted by permission.)

for the CYSHCN who often require not only multiple medical specialists, but also medical home team and community partners (e.g., educators, therapists, home health providers, and behavioral and developmental specialists) to communicate and work together to achieve the best outcomes for the child and their family. “Care coordination addresses interrelated medical, social, developmental, behavioral, educational and financial needs to achieve optimal health and wellness outcomes” (Antonelli, McAllister, & Popp, 2009, p. vii). Box 41.1 outlines the framework for highly performing pediatric care coordination. Infrastructure building is needed to create a high-functioning team to effectively integrate care for CYSHCN. There are various models and locations to create these care coordination teams, which necessitate effective resourcing and payment models (Kuo, McAllister, Rossignol, Turchi, & Stille, 2018).

The Agency for Healthcare Research and Quality (2015) notes that while all patients are likely to benefit from the basic elements of care coordination

BOX 41.1 EVIDENCE-BASED PRACTICE**A Framework for Highly Performing Pediatric Care Coordination****Care Coordination Definition**

Pediatric care coordination is a patient- and family-centered, assessment-driven, team-based activity designed to meet the needs of children and youth while enhancing the caregiving capabilities of families. Care coordination addresses interrelated medical, social, developmental, behavioral, educational, and financial needs in order to achieve optimal health and wellness outcomes.

Defining Characteristics of Care Coordination

1. Patient and family centered
2. Proactive, planned, and comprehensive
3. Promotes self-care skills and independence
4. Emphasizes cross-organization relationships

Care Coordination Competencies

1. Develops partnerships
2. Proficient communicator
3. Uses assessments for intervention
4. Facile in care planning skills (PFC)
5. Integrates all resource knowledge
6. Possesses goal/outcome orientation
7. Approach is adaptable and flexible
8. Desires continuous learning
9. Applies solid team-building skills
10. Adept with information technology

Care Coordination Functions

1. Provide separate visits and care coordination interactions
2. Manage continuous communications
3. Complete/analyze assessments
4. Develop care plans (with family)
5. Manage/track tests, referrals, and outcomes
6. Coach patient/family skills learning
7. Integrate critical care information
8. Support/facilitate all care transitions
9. Facilitate PFC team meetings
10. Use health information technology for care coordination

From Antonelli, R. C., McAllister, J. W., & Popp, J. (May 2009). *Making Care Coordination a Critical Component of the Pediatric Health System: A Multidisciplinary Framework*. The Commonwealth Fund; reprinted by permission.

(i.e., effective communication and efficient exchange of information among care providers), from a purely efficiency standpoint patient populations with special needs and medical complexity would likely benefit the most from robust care coordination approaches. The following are three key strategies for effective and efficient care coordination:

1. Identify population(s) with needs that are likely to be addressed by care coordination activities
2. Align services directed to the needs of the patient population being served
3. Properly prepare and integrate appropriate personnel to deliver the needed services

It should be noted that the payment aspect for delivering care coordination services remains an unresolved issue and is discussed in more detail below. When care coordination is provided by an insurer

or health plan as part of a case management team located in the insurance company, the costs are seen as operational expenses; however, when the health care provider delivers the care coordination services in the high-performing medical home, the additional essential staff and services may not be reimbursable expenses at the practice level.

An American Academy of Pediatrics policy statement on care coordination defines essential characteristics of care coordination as having 1) family-centeredness; 2) a planned, proactive, and comprehensive focus; 3) promotion of self-care skills and independence as a priority; and 4) an emphasis on cross-organizational relationships (American Academy of Pediatrics, 2014). Care coordination addresses primary and specialty medical care, hospital transitions, setting goals with patients and families, and accessing community resources. Taking care coordination one step further fosters care integration that is “the

seamless provision of health care services, from the perspective of the patient and family, across the entire care continuum. It results from coordinating the efforts of all providers, irrespective of institutional, departmental, or community-based organizational boundaries" (Antonelli, 2015 p. 6). The Agency for Healthcare Research and Quality provides an instructive graphic to explain the characteristics of care coordination as seen from the perspectives of the patient and family, the health care provider, and the health care system (see Figure 41.4).

According to the 2016 National Survey of Children's Health, slightly less than half (49%) of children were found to be receiving coordinated, ongoing comprehensive care within a medical home. Among the survey respondents indicating a need for care coordination, 72% stated they received needed care coordination. Care coordination can have a favorable impact on the family's experience. An analysis of the NS-CYSHCN in 2005–2006 found that those children who received adequate care coordination had an increased chance of receiving family-centered care, experiencing partnerships with professionals, and indicating satisfaction with services (Turchi et al., 2009).

In an attempt to deal with these issues, insurers, hospitals, and public and private agencies have developed case management programs. The purpose and scope of these programs, however, vary with agency type and often are not focused on the overall coordination of care. As an example, a hospital case management program generally deals with patients at one point in time (i.e., at discharge from a hospital stay) and does not address the patient's needs beyond the hospital episode. Hospitals currently use case managers principally to provide information to payers and assist with discharge planning. In the era of health care reform, however, the case manager's job description may broaden in the context of an accountable care organization (ACO; Watson, 2016). Case managers working for insurers and managed care organizations (MCOs) typically focus more on benefits management and resource utilization and less on care coordination, although some Medicaid MCOs do organize and coordinate a broader package of benefits (Abt Associates, 2000). Many social agencies and public programs provide case management services as these are often mandated by public policy. Title V programs are one of the largest federal block programs, distributing funds to 59 states and jurisdictions. Several of the objectives of Title V funding include, but are not limited to provide "access to preventive and child care services as well as rehabilitative services for children in need of specialized medical services and to provide family-centered,

community-based systems of coordinated care for children with special healthcare needs" (U.S. Department of Human Services, 2018). Maternal child health agencies and states submit applications for funds, and, if awarded, they are required to conduct and/or implement needs assessments, reports, and outcomes based on national outcome measures, national performance measures, and evidence-based strategies. While a portion of funds allocated to each entity needs to be spent on CYSHCN, the exact programming and specific efforts are informed by the needs assessments and constituents in each respective agency and state.

Although Medicaid payment for case management may be allocated for a child, families may find that their case manager lacks the necessary medical knowledge or does not communicate adequately with their child's clinicians. Many specialty programs in children's hospitals have nurse specialists who help coordinate the medical care. These specialty-based care coordinators may have comprehensive information about the particular disorder (e.g., diabetes) but may lack knowledge about community- or primary care-level resources and other aspects of comprehensive medical care. This points to the importance of providing care coordination at the community practice (medical home) level. One of the few estimates of the cost of providing care coordination services in a community-based practice suggested that, although substantial, it is not cost prohibitive (Antonelli & Antonelli, 2004).

An important question is whether the increased cost of coordinated care produces better outcomes. There is some evidence to support the value of care coordination in inpatient and family-centered medical homes (Farmer et al., 2011; Long, Bauchner, Sege, Cabral, & Garg, 2012; Mosquera et al., 2014). Effective care coordination may occur in a number of different settings and often is directed toward CYSHCN because they utilize more resources than typically developing children (Kuo et al., 2018). In some studies, findings include fewer emergency department visits, a decreased family financial burden with fewer out-of-pocket expenses, fewer missed days of school and work for the child and caregivers, and improved caregiver-reported satisfaction (Farmer et al., 2011; Long et al., 2012; Mosquera et al., 2014). However, while this may prove cost-effective for the family and insurer, in half the cases, care coordination is often an unreimbursable service for the provider (Antonelli & Antonelli, 2004; Antonelli, Stille, & Antonelli, 2008). It should be noted that even when care coordination is available, many services may not be located in convenient, community-based settings, thus further depleting the family's energy and resources.

Figure 41.4. Care coordination graphic. (From McDonald, K. M., Schultz, E., Albin, L., Pineda, N., Lonhart, J., Sundaram, V., Smith-Spangler, C., Brustrom, J., Malcolm, E., Rohn, L., & Davies, S. Care Coordination Atlas Version 4 [Prepared by Stanford University under subcontract to American Institutes for Research on Contract No. HHS290-2010-00005]. AHRQ Publication No. 14-0037- EF. Rockville, MD: Agency for Healthcare Research and Quality. June 2014. [AHRQ Chapter 2, Pg 9].)

Care Planning

The role of the team in care coordination emphasizes the importance of multiple roles, including parents/caregivers, primary care providers, care coordinators, health care specialists, educators, pharmacists, mental health providers, and community partners (Chen et al., 2010; Katkin et al., 2017). The shared responsibility of team members fosters efficiency in planning before, during, and after a patient encounter and includes clinicians, medical assistants, nurses, and office staff (see the text-box titled What Care Planning Involves; Katkin et al., 2017). Staff roles and contributions should be defined and understood by all members (Phillips, Hebish, Mann, Ching, & Blackmore, 2016; see Box 41.2). In addition, practice teams can engage in “huddles” prior to a patient visit where discussions around needed services, planning for the visit, and communication about health events since the patient and family were last in the office are all important (Rodriguez et al., 2015). Often the team can utilize patient registries to identify the CYSHCN who require additional supports, services, or care integration across teams or settings to best serve them and their families (Davis, McFadden, Patterson, & Barkin, 2015). Registries can be created within electronic health records and managed with shared folders among the team. This fosters collaboration with care

team members in the community (e.g., therapists, educators in the school system, home health agencies, and behavioral health providers). Training teams and family members about the value and role of care planning is essential. Measuring care coordination activities and experiences across all members of the team can be effective and assist in more efficient time management and patient flow (Ferrari, Ziniel, & Antonelli, 2016).

What Care Planning Involves

- Multiple providers and services across many disciplines
- Summaries and guidelines for current and future health issues to foster communication among all the disciplines caring for the child and his/her family
- Coordination with community partners, home care agencies, and therapists
- Contingency planning for CYSHCN during emergencies and unanticipated health problems
- A summary of medical diagnoses, medications, equipment, specialists, therapists, educational needs, child/youth strengths, transition needs, and contact information

BOX 41.2 INTERDISCIPLINARY CARE

The Role of the Care Coordinator

Role	Location
• Assist patient and families in navigating the health care system and community resources • Develop and maintain care plans and care planning for patients and families • Coordinate patient care services and appointments • Advocate for needed resources and services with agencies and insurance companies • Set goals with patients and families • Ensure patient goals are met and patients/families are satisfied and have consistent comprehensive care • Facilitate effective transitions of care from inpatient to outpatient settings • Foster successful transitions from pediatric- to adult-oriented systems • Collaborate with nonmedical services needed for patients and families (e.g., therapies, education, and behavioral/mental health) • Ensure patient- and family-centered care goals are met and incorporate tenets of medical home and care integration across all aspects of care	• Primary care medical home • Specialty office • Insurance company • Community based • Agencies (e.g., early intervention and behavioral health)
Background/Training	
• Nurses • Social workers • Parent partners • Referral coordinator • Curricula available (citations below)	

Sources: American Academy of Pediatrics (2014); Boston Children's Hospital (2013); Conway, O'Donnell, and Yates (2017); and Weaver, Che, Petersen, and Hysong, (2018).

- Clearly identified aspects of the child's health that are likely to get better or worse over time for the purpose of future planning
- Clearly noted exacerbations of the chronic condition the child is likely to experience and what acute illnesses he/she may be at enhanced risk for (e.g., flu)
- Clearly identified new co-occurring conditions the child is likely to develop and how they can be avoided or treated early
- Assessment of the family functioning, stress, and social determinants of health
- Discussion of major medical interventions the child and family will likely face over time
- Development of family goals for their child over the next 1, 5, and 10 years

Approaching care planning using a patient- and family-centered care lens fosters engagement and ensures efficiency. The publication *Achieving a Shared Plan of Care with Children and Families with Special Health Care Needs* provides a road map for health care teams and families in developing a shared, written plan of care with the support of a high-level, team-based care coordinator (McAllister, 2014). This shared plan of care is informed by family goals and team concerns, merging them into a strategic plan of action to use/follow. Families need to be involved in all aspects of the system "frontlines," from designing systems to implementation, outcome assessment and evaluation, and policy dissemination (Allshouse, Comeau, Rodgers, & Wells, 2018). Outlining and guiding subsequent care coordination activities and contingency planning in an emergency are key aspects to be achieved in partnership with families over time. One study examined the impact of a hospital-based multidisciplinary team's comprehensive needs assessment and the creation of individualized shared care plans on the quality and cost outcomes for CMC and their families. It demonstrated improved family experience of care, but the CMC cohort incurred increased costs with no improvement in functional outcomes compared with the nonintervention cohort (Simon et al., 2017). Given the service needs and multiple providers, patients and families should be engaged as partners at all levels of care coordination and decision making, including goal setting, care planning, care gaps, and assessing their experiences (Cene et al., 2016). Several validated instruments can assist in measuring the patient and caregiver experience (Walker, Stewart, & Grumbach, 2016; Ziniel et al., 2016), and there are existing tools for care

coordination activities, including flexible and modifiable care coordination curricula for training health care teams in developing competencies. These skills include care planning, integration with behavioral health, and safe transitions of care, such as transitioning from inpatient to outpatient settings and from the pediatric to the adult sector (Boston Children's Hospital, 2013).

The social determinants of health are defined by the Centers for Disease Control and Prevention (2018, para. 1) as "conditions in the places where people live, learn, work and play that affect a wide range of health risks and outcomes," and they have been shown to be influencers of health outcomes and potential drivers of health care costs (Booske, Athens, Kindig, Park, & Remington, 2010). For example, patients with unmet needs may have increased emergency department utilization and higher rates of no-show appointments (see Chapter 42; Berkowitz et al., 2016; Garg et al., 2013). Screening for social determinants of health within the pediatric medical home model can assist in appropriate resource allocation and ensure that patient and family needs are met (Garg et al., 2007). Screening for social determinants in the population of CYSHCN requires selecting a tool or questions that adequately address the patient population in embedded electronic health records or streamlined systems, communicating appropriately with patients about the social determinants of health, having resources and referral networks to meet the needs of the patients served, and utilizing care integration across systems (both medical and nonmedical) to communicate needs and foster integration (Thomas-Henkel & Schulman, 2017). Community health workers have been identified as a possible resource to assist in interventions with families and have been associated with favorable impacts on health care outcomes (Mathu-Muju, Kong, Brancato, McLeod, & Bush, 2018; Mundorf et al., 2018).

CHANGES IN FINANCING HEALTH CARE FOR CYSHCN

There are several perspectives on what constitutes an optimal health care system for CYSHCN and CMC. For most of its history, the health care system in the United States has utilized a fee-for-service (FFS) model in which the health care provider receives a payment for each unit of service rendered (MacLeod, 2001). In an FFS payment model, the health care provider is compensated for the volume of covered services delivered and not necessarily for the quality or measured outcome of those services. Therefore, a great deal of effort is directed toward counting the specific procedures and services provided during the encounter. In response to skyrocketing costs and general displeasure with the quality of care delivered in the existing FFS system in

the United States, reformers have called for a shift from this volume of service, or counting, approach to reimbursement to a model that seeks instead to reimburse for the quality of the care delivered. The ultimate goal is a value-based model that pays for achieving actual positive outcomes for the patient. The equation for value in health care is $\text{value} = \text{quality} / \text{cost}$. The drive toward paying for quality and outcomes in health care would seem well suited for CYSHCN and CMC, whose health care costs may be as high as three times that of children in the general population (Newacheck & Kim, 2005).

The Centers for Medicare and Medicaid Services (2015) has developed a four-category framework to describe a progressive shift from FFS toward value-based reforms:

1. FFS with no link to quality
2. FFS linked to quality
3. Alternative payment models (APMs) built on an FFS architecture
4. Population-based payment

Figure 41.5 describes the framework and time frame over which the Centers for Medicare and Medicaid Services (CMS) envision the U.S. health care system adopting so-called APMs. CMS is focused initially on the Medicare system, but the expectation is that Medicaid as well as much of the commercial insurance system will likely eventually embrace this effort. In considering the potential benefit of these APMs as they apply to children and adolescents, Dr. Sandra Hassink (2015), then president of the American Academy of Pediatrics, highlighted the longitudinal value of pediatric quality and preventive measures. She noted specifically that the return on investment should not be limited to a benefit plan year since much of the potential benefit may extend beyond that period (e.g., obesity prevention). Clearly, a focus on value of care delivered rather than on the delivery of a volume of services has the potential to be useful in promoting medical homes for CYSHCN and CMC. A value-based approach would likely avoid the challenges of counting and billing for specific services and would instead provide a pathway for the care coordination and related services necessary for ideal care. A value-based approach would likely generate cost savings that can be redirected toward the care coordination so essential to delivering effective medical home care (Agency for Healthcare Research and Quality, 1997). Berry and colleagues (2013) noted a number of examples supporting the value of clinical programs designed to coordinate care and optimize health; Table 41.2 summarizes these promising examples.

One of the principal proposals of health care reform is the development of ACOs. An ACO is defined as follows:

A group of physicians, other healthcare professionals, hospitals, and other healthcare providers that accept a shared responsibility to deliver a broad set of medical services to a defined set of patients across the age spectrum and who are held accountable for the quality and cost of care provided through alignment of incentives. (American Academy of Pediatrics, 2011, p. 1)

An ACO would be given annual funding on a per-capita basis for providing comprehensive care. In this shared-risk model, if the ACO does not need to expend all the money, it is permitted to keep a portion; however, if it spends more, it is responsible for the financial loss. The foundation of ACOs lies in the primary care medical home and, if adopted, will drive the health care financial discussion in the next decade.

In the current FFS model, care for CYSHCN fosters volume-driven payments that do not adequately support non-face-to-face time, such as care coordination services. Moving toward alternative payment models (e.g., value-based payments, population health, or bundled per-member/per-month models) affords the health care arena an opportunity to explore new payment opportunities for CYSHCN. A shift to a population health framework with high-functioning medical homes and care integration will foster alternative payment models, allowing the care of CYSHCN to best meet their needs. To accomplish this goal, a paradigm shift for this population is needed to include risk stratification (Simon et al., 2014) so that it involves both medical and nonmedical services and communication and coordination with nonmedical partners, addressing the social determinants of health and benchmarking quality for a unique population not fitting into the framework for typically developing children (Langer, Antonelli, Chamberlain, Pan, & Keller, 2018). For example, CYSHCN may have a level of complexity where care coordination reduces the risk of readmissions, but they still may require hospitalizations for some of their intrinsic medical issues. However, addressing effective hand-offs, transitions of care, and post-hospital discharge follow-up may allow for a shared savings for care providers. In addition, utilizing health information exchanges, patient portals, and effective communication may enhance this process. Caring for CYSHCN may also allow for risk-stratified capitation payments to address the added effort and time required to provide high-quality care to this fragile population. These payments could include but not be limited to care coordination, screening, and supporting patient and family engagement, further aligning with the Quadruple Aim (Langer et al., 2018).

Aim: When it comes to improving the way providers are paid, we want to reward value and care coordination rather than volume and care duplication. In partnership with the private sector, the Department of Health and Human Services is testing and expanding new health care payment models that can improve health care quality and reduce its cost.

Payment taxonomy framework

	Category 1 Fee for services (FFS)—no link to quality	Category 2 FFS—link to quality	Category 3 Alternative payment models built on FFS architecture	Category 4 Population-based payment
Description	<i>Payments are based on volume of services and not linked to quality or efficiency.</i>	<i>At least a portion of payments vary based on the quality or efficiency of health care delivery.</i>	<i>Some payment is linked to the effective management of a population or an episode of care. Payments are still triggered by delivery of services, but there are opportunities for shared savings or 2-sided risk.</i>	<i>Payment is not directly triggered by services delivery so volume is not linked to payment. Clinicians and organizations are paid and responsible for the care of a beneficiary for a long period (e.g., greater than 1 year).</i>
Medicare FFS	Limited in Medicare FFS Majority of Medicare payments are now linked to quality	Hospital value-based purchasing Physicians value-based modifier Readmissions/hospital-acquired condition reduction program	Alternative payment models built on FFS architecture Some payment is linked to the effective management of a population or an episode of care. Payments are still triggered by delivery of services, but there are opportunities for shared savings or 2-sided risk. Accountable care organizations Medical homes Bundled payments Comprehensive primary care initiative Comprehensive Comprehensive end-stage renal disease (ESRD) Medicare–Medicaid financial alignment initiative FFS model	Eligible pioneer accountable care organizations in Years 3–5

Value-based purchasing includes payments made in Categories 2 through 4. Moving from Category 1 to Category 4 involves two shifts: (1) increasing accountability for both quality and total cost of care and (2) a greater focus on population health management as opposed to payment for specific services.

Timeline

Target percentage of Medicare FFS payments linked to quality and alternative payment models in 2016 and 2018

All alternative payment models and payment reforms that seek to deliver better care at lower costs share a common pathway for success: Providers must make fundamental changes in their day-to-day operations that improve quality and reduce costs. Making operational changes will be attractive only if the new alternative payment models and payment reforms are broadly adopted by a critical mass of payers. When providers encounter new payment strategies for one payer but not others, the incentives to fundamentally change are weak. In fact, a provider that alters its system to prevent admissions and succeeds in an alternative payment environment may lose revenue from payers that continue FFS payments.

Figure 41.5. Framework for value-based reimbursement evolution (Agency for Healthcare Research and Quality, 1997; Centers for Medicare and Medicaid Services, 2015).

(continued)

Figure 41.5. (continued)

The key elements of value-based purchasing include:

- **Contracts** spelling out the responsibilities of employers as purchasers with selected insurance, managed care, and hospital and physician groups as suppliers.
- **Information** to support the management of purchasing activities.
- **Quality management** to drive continuous improvements in the process of health care purchasing and in the delivery of health care services.
- **Incentives** to encourage and reward desired practices by providers and consumers.
- **Education** to help employees become better health care consumers.

Agency for Healthcare Research and Quality (1997)

Table 41.2. Examples of clinical programs designed to coordinate care and deliver value

Location	Description and citation
Complex Medical Care Program at University of Texas, Houston	Randomized clinical trial of high-risk children with chronic illness (defined as having at least 3 emergency department visits, 2 hospitalizations, or 1 pediatric intensive care unit admission during the previous year, and a 50% or higher estimated risk for hospitalization) treated at a high-risk clinic at the University of Texas, Houston, and randomized to comprehensive care (n = 105) or usual care (n = 96). Enrollment was between March 2011 and February 2013 (when predefined stopping rules for benefit were met), and outcome evaluations continued through August 31, 2013. Mosquera, R. A., Avritscher, E. B., Samuels, C. L., Harris, T. S., Pedroza, C., Evans, P., . . . Moody, S. (2014). Effect of an enhanced medical home on serious illness and cost of care among high-risk children with chronic illness: A randomized clinical trial. <i>JAMA</i> , 312(24), 2640–2648.
Two community-based pediatric clinics in Canada staffed with tertiary-care nurse practitioners to coordinate care	Eighty-one patients with medical complexity reported a mean (standard deviation [SD]) decrease in per-member/per-month (PPPM) total health system costs from \$244 (SD 981) to \$131 (SD 335) without an increase in out-of-pocket costs to families. Fewer inpatient days was the primary reason for the decrease PPPM. Child quality of life improved after enrollment in the clinic intervention. Cohen, E., Lacombe-Duncan, A., Spalding, K., MacInnis J, Nicholas D, Narayanan, U. G., . . . Friedman J. N. (2012). Integrated complex care coordination for children with medical complexity: A mixed-methods evaluation of tertiary care-community collaboration. <i>BMC Health Services Research</i> , 12, 366.
Outpatient primary care program for children with medical complexity at Arkansas Children's Hospital	Reported a 1-year decrease in the mean annual cost per-patient-per-month (PPPM) of \$1,800 for inpatient care and \$6 for emergency department care. Although PPPM cost for outpatient claims and prescriptions increased, the overall cost to Medicaid PPPM decreased by approximately \$1,200. Casey, P. H., Lyle, R. E., Bird, T. M., Robbins, J. M., Kuo, D. Z., Brown, A., Tanios, A., & Burns, K. (2011). Effect of hospital-based comprehensive care clinic on health costs for Medicaid-insured medically complex children. <i>Archives of Pediatric and Adolescent Medicine</i> , 165(5), 392–398.
A medical home program for children with complex disease at the University of California, Los Angeles	30 CMC were offered a 1-hour intake appointment, 30-minute follow-up visits, access to a family liaison, and a family notebook; they reported a decrease in the average number of emergency department visits from 1.1 (SD 1.7) to 0.5 (SD 0.9) in the 1 year after enrollment. Klitzner, T. S., Rabbitt, L. A., & Chang, R. K. (2010). Benefits of care coordination for children with complex disease: A pilot medical home project in a resident teaching clinic. <i>Journal of Pediatrics</i> , 156(6), 1006–1010.
Outpatient consultative program at the Children's Hospital of Wisconsin	Provided intensive care coordination for approximately 230 CMC; reported a \$400,000 annual loss to operate the program, while contributing to a 3-year reduction in hospital resource utilization of more than \$10 million for its patients. Gordon, J. B., Colby, H. H., Bartelt, T., Jablonski, D., Krauthoefer, M. L., & Havens, P. (2007). A tertiary care-primary care partnership model for medically complex and fragile children and youth with special health care needs. <i>Archives of Pediatric and Adolescent Medicine</i> , 161(10), 937–944.
Six primary care pediatric practices in Massachusetts	A care coordination intervention for approximately 150 CMC/CSHCN that included a case manager, parent consultant, and an individualized plan of care was associated with a decrease in hospitalization rate (58%–43%) and a decrease in the rate of parents missing 3 or more weeks of work (26%–14%). The intervention cost \$400 per patient. Palfrey, J. S., Sofis, L. A., Davidson, E. J., Liu, J., Freeman, L., & Ganz, M. L. (2004). The Pediatric Alliance for Coordinated Care: Evaluation of a medical home model. <i>Pediatrics</i> , 113(Suppl. 5), 1507–1516.

Source: Berry, Agrawal, Cohen, and Kuo (2013).

Insurance Coverage: Public and Private

The federal and state governments provide several other avenues for CYSHCN and CMC and their families to gain access to a range of health care services and funding for these services. These include 1) the Social Security Administration's Supplemental Security Income program that provides income support and/or access to Medicaid; 2) the MCHB's Title V programs, which support systems and provide services in some areas for CYSHCN; and 3) the Individuals with Disabilities Education Improvement Act of 2004 (PL 108-446), which links educational and health care needs with Medicaid funding. However, in practical terms, these programs can have considerable state-to-state variability in eligibility criteria, types of services covered or offered, and amount of care provided.

Where CYSHCN and CMC get their insurance is an important aspect of the financing for their care. According to the Kaiser Family Foundation (Musumeci, 2017), Medicaid and other public health insurance programs cover 44% of CYSHCN and CMC. In addition, publicly funded insurance is the sole source of funding for 36% of CYSHCN and CMC; an additional 8% have public insurance as a supplement to their private coverage. Figure 41.6 arrays the types of health insurance among CYSHCN and CMC.

Figure 41.6. Type of health insurance for children with special health care needs. (From Musumeci M. *Medicaid and Children with Special Health Care Needs*. The Henry J. Kaiser Family Foundation Issue Brief. January 2017. <http://files.kff.org/attachment/Issue-Brief-Medicaid-and-Children-with-Special-Health-Care-Needs>; reprinted by permission.)

The cost trends described above are expected to increase as a function of an increased prevalence of CYSHCN and CMC. For example, between 2001 and 2011, there was a 15.6% increase in children with neurodevelopmental and mental health conditions, accounting for the largest increases in chronic conditions during this time frame (Houtrow, Larson, Olson, Newacheck, & Halfon, 2014).

Wagner (1998) has proposed a chronic care model focusing on patient-provider interactions. The model underscores how favorable outcomes for patients, families, and practice teams ensue when the medical home works in partnership with community resources and policies. Figure 41.7 provides a graphic representation of Wagner's chronic care model, the characteristics of which include the following:

- Providing care in the context of a medical home
- Having processes and incentives to improve the care delivery system
- Having information technology and clinical decision support for clinicians
- Ensuring a focus on effective self-management training and support
- Organizing team activities and practice systems around the unique needs of children, youth, and adults with chronic conditions
- Utilizing appropriate evidence-based guidelines in a measurable manner
- Fostering increased communication between primary care and specialty care providers

Figure 41.7. Wagner's chronic care model. (From Wagner. [1998]. "Chronic disease management: What will it take to improve care for chronic illness?" *Effective Clinical Practice*, August/September, 1: 2-4; reprinted by permission.)

- Utilizing information systems in a way that produces disease registries, tracking systems, and reminders about important care needs
- Providing care in the environment of a patient- and family-centered medical home

The Centers for Medicare and Medicaid Services, which have federal oversight and responsibility for Medicaid, have established a set of safeguards promoting attention to the unique aspects of caring for CYSHCN and CMC in the current health care environment. To deal with this issue, some states have conceived of “carve-outs” for these children in which the child is handled separately from the general population. CYSHCN also may be eligible for various Medicaid waivers, including 1) the Home and Community-Based Services Waiver, sometimes referred to as a 1915(c) waiver, and 2) the Katie Beckett waiver (Peters, 2005). Both essentially waive, or permit exceptions to, certain federal requirements to provide home- and community-based services as an alternative to institutionalization or continued hospitalization. Such waivers, for example, may permit a family with a CYSHCN or CMC to receive Medicaid in order to access health care services and support for keeping that child at home rather than in a hospital or chronic care facility. One advantage of the waivers is that family income may be exempted from consideration in determining eligibility for Medicaid. The waivers are state-run programs, however, so each state has different approaches to waivers with different eligibility requirements or services. Examples of disorders/diagnoses that may qualify for CYSHCN/CMC waivers include children/youth with intellectual disability, those who are dependent on home nursing services, those with technology dependence or need for mobility aids, and those with autism spectrum disorder (ASD).

Looking to the Future

Classically, the measurable dimensions of health care quality are the structure, the process, and the actual outcomes (Donabedian, 1980). Structure, from a quality and health services perspective, describes aspects of the health care system such as facilities, staffing patterns, and qualifications. Process in this context deals with the policies and procedures that govern aspects of care, such as technical and professional skills, documentation of care, safety practices, and the use of assessment tools. Finally, outcomes deal with the health status of the people served, their health-related knowledge and behavior, and their satisfaction with the care they receive (Monahan & Sykora, 1999). Looking at one

special health care need, ASD, the Waisman Center at the University of Wisconsin undertook the National Medical Home Autism Initiative and issued a 47-page document, titled *Medical Home Services for Autism Spectrum Disorders* (2008), which articulates how the medical home concept can be applied to patients and families with ASD. The appendix to this chapter lists five guidelines and addresses recommendations at the family, professional, and governmental levels. See Appendix D in the book's online materials for more valuable resources for both families and professionals to use in assisting CYSHCN and CMC locate and manage their medical home and the care coordination services they need.

SUMMARY

- Coordinating health care services for CYSHCN and CMC presents a unique challenge to the child's family and health care providers.
- The complexity of the child's needs necessitates time, energy, and skill to coordinate the efforts of different agencies, institutions, and professionals so that they work effectively together in a comprehensive plan of care.
- This coordination is particularly complex because of the labor-intensive nature of the comprehensive case management necessary and because the child's needs may span a range of services, including some that are not traditionally seen as health related.
- Further complicating matters are the many federal and state agencies and programs involved in providing and funding services and the revolutionary changes currently occurring in the health care marketplace.
- All of this points to the importance of each child having a high-quality medical home complete with addressing population health, an interdisciplinary team working with community partners and across systems, patient- and family-centered care, and effective care coordination and integrated care to assist the family in navigating this complex system.

APPENDIX

Waisman Center's Medical Home Services for Patients with Autism Spectrum Disorder (ASD)

Guidelines	Recommendations		
	Individuals with ASD and their family	Professional and training organizations	Government and finance agencies
1. The medical home—primary care practice (MH-PCP) is aware of and implements medical home (MH) principles when caring for children and youth, including those with ASD.	Youth with ASD and their parents serve as teachers and mentors in medical school residency training and continuing education programs and contribute to the development of curriculum and office management tools to help prepare the MH-PCP practice for serving families with ASD.	Accreditation/residency and training programs recognize the importance of the MH principles by including MH practice training as a required component of pre-med, residency, and continuing education curriculum for pediatrics, family medicine, med-peds, and midlevel providers such as nurse practitioners and physician assistants. Board licensing and recertification requirements include MH principles, especially as they relate to the care of patients with ASD and other chronic conditions. Accreditation/residency and training programs include out-of-office/hospital rotations at the community level in service settings and in the homes of children, youth, and families with ASD and other chronic conditions. Professional organizations such as the American Academy of Pediatrics (AAP), the American Academy of Family Physicians (AAFP), and the National Association of Pediatric Nurse Practitioners (NAPNP) provide ongoing continuing medical education training in the principles and implementation of an MD for the care of all children/youth, including those with ASD.	Funders/insurers and other health care payers reimburse MH-PCPs for the extra time required to provide a quality MH to children/youth. This includes the elements of planned care such as care coordination, comanagement with specialists, and collaboration with community agencies required when children have developmental disorders such as ASD.

(continued)

Guidelines	Recommendations		
	Individuals with ASD and their family	Professional and training organizations	Government and finance agencies
2. The MH-PCP is organized in a manner that involves the entire office staff in meeting the complex needs of the patient with ASD and his or her family and offers flexibility in the provision of services.	Youth with ASD and their parents serve as resources and mentors to the MH-PCP administrative and medical staff who schedule appointments and receive ASD families at the office, helping to overcome communication and social barriers (e.g., by providing communication-assisted technology for children or youth who are nonverbal) and address special family needs related to ASD. Families and advocacy groups advocate for improved reimbursement and funding to adequately compensate primary practice providers for the additional time and resources needed to educate and prepare all office staff to serve families with children with ASD, involving the families as mentors and partners with the primary practice.		Accreditation/residency and training programs emphasize the important role of staff at all levels of the practice in serving children with special health care needs such as ASD and prepare staff for their roles in office-based practices.
3. The MH-PCP, in collaboration with subspecialists and community agencies, provides appropriate disorder-specific information (printed, electronic, etc.) on all aspects of ASD, including definition, diagnosis, etiology, genetic, neuropath correlates, and developmental and behavioral characteristics to consumers and other community providers.	Families and advocacy groups serve as resources to MH-PCP professionals and to other families in order to share knowledge and information about their personal experiences with ASD and strategies they have used for treating ASD.	Accreditation/residency and training programs emphasize the importance of education materials to increase knowledge and skills of families and caregivers about all aspects of ASD and teach residents methods for retrieving appropriate evidenced-based and consensus-based materials for distribution to patients' families. Professional organizations such as the AAP, AAFP, and NAPNP engage experts in various fields to develop evidenced-based training materials for distribution to parents by MH-PCPs.	Funders/insurers and other health care payers recognize the need for the additional value of offering materials, information, and training to families.
4. In accordance with the principles of family-centered care, the MH-PCP recognizes parents as valued partners and decision makers in the care of their child and establishes regular, ongoing communication with reciprocal exchange of information. An important component of parent-professional partnerships is listening and acting upon parent concerns about their child's development and/or behavior. The physical health and emotional well-being of the entire family is included and considered in all decision making.	Families in a collaborative partnership with MH-PCP providers are informed about federal, state, and local financing options; insurance benefits; and reimbursement mechanisms for chronic conditions and ASD so that they can fully consider insurance and other financing options in efforts to maximize funding of services for children and youth with ASD.	Accreditation/residency and training programs recognize the importance of training activities in parent-professional partnerships and require all residency programs to implement one of the nationally recognized, parent-led curricula. For pediatricians, this might ideally be done during mandatory developmental pediatric rotations using existing curricula developed by parent advocates (e.g., Delivery of Chronic Care Program now existing in 20 states).	Government recognizes and/or appoints a lead public agency to organize and support a system of electronic communication (such as a web page) as a resource to provide current information on ASD and ASD-related services to parents and professionals statewide. A service agency should support this participation with families who do not have access to the Internet.

Guidelines	Recommendations		
	Individuals with ASD and their family	Professional and training organizations	Government and finance agencies
5. The MH-PCP respects and competently serves the multiple and diverse cultures of children with ASD and their families. The practice is linguistically competent, including having culturally appropriate written materials and translators available.	Families with diverse cultural backgrounds assess materials, educational booklets, and the overall cultural competency of MH-PCP practice. They also participate as trainers in efforts to strengthen cultural competency in serving children and families with ASD from diverse backgrounds.	Professional organizations and other training programs provide professional development for office personnel and support staff that includes training to increase the sensitivity, awareness, and understanding of cultural norms and prepares staff to competently serve a culturally diverse client population.	Funders/insurers and other health care payers compensate primary practices for appropriate on-site translators (including sign language) and other resources to ensure that there is appropriate language proficiency, signage, and written materials in the practice setting.

CHAPTER 42

Racial and Ethnic Disparities

Olanrewaju O. Falusi, Monika Goyal, Elissa Batshaw Clair, Catherine Larsen Coley, Susan Keller, Mary A. Hadley, and Denice Cora-Bramble

Upon completion of this chapter, the reader will

- Describe the complex relationship between childhood disabilities and health and educational disparities
- Recognize successful initiatives to achieve health and educational equity
- Perform a self-assessment of implicit bias
- Incorporate principles of health and educational equity into clinical practice and advocacy efforts

■ ■ ■ CASE STUDY

Miguel is a 4-year-old Hispanic male recently diagnosed with autism and seeing a speech therapist for the first time. The speech therapist mentions to Miguel's mother, Maria, that she is surprised that he is just starting to receive therapy as most children with autism are diagnosed and start therapy at an earlier age. Maria says she had concerns about his delayed speech and social interactions since he was 2 years old but that their pediatrician was not concerned. Maria confides that she does not feel that the pediatrician spent enough time hearing out her concerns. The pediatrician eventually referred Miguel to a developmental pediatrician when he still had only five words and poor social skills at age 3 years. Miguel has Medicaid insurance coverage and due to a lack of Medicaid-accepting providers in their area, they waited 9 months before seeing a developmental pediatrician who diagnosed him with autism and another 3 months for a speech therapy appointment and special education placement.

Thought Questions

How does a child's race/ethnicity affect his or her access to quality, culturally appropriate health care? How can clinicians examine and address their own implicit or unconscious biases? What factors underlie the racial disproportionality in special education? How can educators examine and address their own implicit or unconscious biases?

DEFINITIONS

As noted in Chapter 12, traditional clinical definitions of disability commonly refer to the individual's functional capacity without explicit regard to the internal (genetic) and external (environmental) factors that may lead to the disability or impact its severity. The National Center for Medical Rehabilitation Research and the World Health Organization (2011) have proposed biopsychosocial models of disability that take into account

elements—such as a family’s financial limitations or environmental barriers—that may impact a person’s ability to achieve optimal function within the disability. A limited, but growing body of literature delves further into the sociocultural factors that may affect the development and treatment of disability and thereby lead to **health disparities** (Bright, Knapp, Hinojosa, Alford, & Bonner, 2016; Schieve, Boulet, Kogan, Van Naarden-Braun, & Boyle, 2011; Spencer & Strazdins, 2015; Thomas, Parish, Rose, & Kilany, 2012).

Although many professionals have an intuitive understanding of the term *health disparity*, there is a lack of consensus on a formal definition of this term (Carter-Pokras & Baquet, 2002; Dehlendorf, Bryant, Huddleston, Jacoby, & Fujimoto, 2010). Most will agree, however, that the term refers to differences in the measures of health and availability of health care across populations. In the United States, the term *health disparities* has generally been assumed to refer to health or health care differences among racial and ethnic groups. For example, the Institute of Medicine (IOM), in their 2002 report on health disparities, “Unequal Treatment,” defines disparities in health care as “racial or ethnic differences in the quality of health care that are not due to access-related factors or clinical needs, preferences, and appropriateness of intervention” (2003, p. 4). The IOM has focused its analysis on health care disparities around race and ethnicity at two levels: 1) the operation of health care systems and the legal and regulatory climate in which health care systems function and 2) discrimination at the individual, patient-provider level. The committee further delineated that discrimination refers to differences in care that result from biases, prejudices, stereotyping, and uncertainty in clinical communication and decision making (Institute of Medicine, 2003).

Health equity has been broadly defined as the absence of socially unjust or unfair health disparities (Braveman & Gruskin, 2003). Unlike equality, in which individuals are treated the same, equity ensures groups and individuals have what they need to reach positive outcomes, as depicted in Figure 42.1. Health equity can further be defined as the absence of systematic disparities in health or social determinants of health among social groups who have different levels of underlying social advantage or disadvantage. Inequities in health systematically put groups of people who are already socially disadvantaged at a further disadvantage with respect to their health. This is important because those who are at higher risk of health inequity, racial/ethnic minorities as an example, become part of a vicious cycle, as health is essential to well-being and to overcoming other effects of social disadvantage (Braveman & Gruskin, 2003).

Figure 42.1. Equality versus equity. (From Maine Center for Disease Control and Prevention. [2018]. What is health equity? Retrieved from <https://www.maine.gov/dhhs/mecdc/health-equity>)

Children with disabilities also comprise a population that often experiences disparities in access to quality care when compared with typically developing children. For example, families of children with disabilities are more likely to encounter delays or frustrations with obtaining needed health, education, and related services, with 35% of families reporting these difficulties (Rosen-Reynoso et al., 2016). From orthopedic disabilities to hearing loss to Down syndrome and intellectual disabilities, families of children with disabilities experience difficulties with respect to transportation, report poorer health status and unmet health and education needs, and are more likely to live in poverty (Boss, Niparko, Gaskin, & Levinson, 2011; Graham, Keys, McMahon, & Brubacher, 2014; Schieve et al., 2011). Although there is a robust body of literature about disparities in health care (Flores & Committee on Pediatric Research, 2010; Institute of Medicine, 2003), published studies focused on health disparities among children with disabilities are much more limited (Houtrow, Okumura, Hilton, & Rehm, 2011; Kuo et al., 2014). When considering health disparities among children with disabilities, racial and ethnic minority children may experience difficulties in two realms: first, they experience a disability, and second, they may experience disparate treatment as a result of membership in an ethnic or racial minority. As a result, minority children with disabilities often experience poorer health status than nonminority children. This chapter will specifically reflect on the complexity of providing health care for racial and ethnic minority children with disabilities who are at the intersection of two disadvantaged populations (Sharby, Martire, & Iversen, 2015). Further, this chapter will review the issue of disparity in regard to the education system for children with disabilities. Health disparities also exist related to gender,

rural/urban location, and other factors, but these are beyond the scope of this chapter.

RACIAL AND ETHNIC HEALTH DISPARITIES IN CHILDREN WITH DISABILITIES

Rates of disability, when broadly defined as a limitation in activity, are higher among black children than non-Hispanic white children, but large, nationwide surveys of children with disabilities have found that the racial correlation is diminished or disappears altogether when adjusted for family income and other social factors, suggesting that poverty rather than race is a key factor in having a disability (McManus, Carle, & Rapport, 2014; Newacheck, Stein, Bauman, Hung, & Research Consortium on Children with Chronic Conditions, 2003). However, racial disparities abound in access to care and health outcomes among children with disabilities. For example, minority children with disabilities are less likely to have a medical home (Conrey, Seidu, Ryan, & Chapman, 2013) and to receive resources for transition to adult care (Richmond, Tran, & Berry, 2012). They are also more likely to utilize emergency care than their white counterparts (Raphael, Zhang, Liu, Tapia, & Giardino, 2009). This in turn affects outcomes, as children without a medical home are more likely to have delayed or forgone care and greater unmet health needs. Their parents report worse coping and are more likely to report loss of work time to meet the medical needs of their children (Drummond, Looman, & Phillips, 2012; Okumura, Van Cleave, Gnanasekaran, & Houtrow, 2009; Strickland et al., 2009).

Health disparities persist even when minority children have access to health care. As depicted in Miguel's case, Hispanic children with autism spectrum disorder (ASD) in one study were diagnosed almost 1 year later

than white children although parents of both ethnicities voiced their concerns to a health care professional at the same age. The Hispanic children in the study also received fewer specialty services and had higher unmet service needs (McManus et al., 2014). In addition, black children with developmental delay at 24 months who are eligible for services have been found to be five times less likely than their white peers to receive services, largely due to differences in identification and referral. This gap in receipt of services is even more striking if the child only has a developmental delay; that is, if the delay is not associated with a more obvious established condition, such as blindness or extreme prematurity (Feinberg, Silverstein, Donahue, & Bliss, 2011).

The 2009–2010 National Survey of Children with Special Health Care Needs (NS-CSHCN), which analyzed data from telephone interviews of a nationally representative sample of over 40,000 parents of CSHCN, provides a view of how race and ethnicity affect the ability of a child with disabilities to access quality care. Table 42.1 provides an overview of the NS-CSHCN study design and demographics; Figures 42.2 to 42.5 depict key study findings related to race/ethnicity (Data Resource Center for Child and Adolescent Health, 2017; U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau, 2013). NS-CSHCN analyses demonstrate that black and Hispanic children with ASD, in particular, are more likely to have difficulties or delays in getting services. One analysis found racial disparities in five out of six quality measures of **family-centered care** in children with ASD: 1) The child does not have a personal doctor or nurse, 2) the doctor does not spend enough time with the child, 3) the provider is not sensitive to the family's values or customs, 4) the doctor does not make the child's parents feel like a partner, and 5) the doctor does not provide enough information. (Only "the doctor does not listen carefully" measure

Table 42.1. National Survey of Children with Special Health Care Needs (CSHCN) survey design and demographics at a glance

Survey design and sponsorship	Maternal and Child Health Bureau at the Health Resources and Services Administration in partnership with National Center for Health Statistics at the Centers for Disease Control, Child and Adolescent Health Measurement Initiative, and a National Technical Expert Panel
Data collection	National Center for Health Statistics at the Centers for Disease Control
Geographic areas	Nationwide, all 50 states and the District of Columbia
Periodicity	2001, 2005–2006, 2009–2010, yearly as of 2016–2017
Population sampled	Noninstitutionalized CSHCN in the United States ages 0–17 years
Sample size range	Nationally: between 38,000 and 40,000; State: approximately 750
Representative	Weighted to be representative of the U.S. population of noninstitutionalized CSHCN ages 0–17 years
Topics	Assesses overall health and health status of CSHCN, including medical home, adequate health insurance, access to needed services, and adequate care coordination. Other topics include functional difficulties, transition services, and shared decision making.

Figure 42.2. National Survey of Children with Special Health Care Needs: Prevalence of CSHCN, by race/ethnicity. (From U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau. [2013]. *The National Survey of Children with Special Health Care Needs chartbook 2009–2010*. Rockville, Maryland: Author. Retrieved from <https://mchb.hrsa.gov/cshcn0910/more/pdf/nscshcn0910.pdf>)

was similar among all groups.) Hispanic parents in particular reported that their doctors did not spend enough time with their children and that they did not feel that the doctors made them partners in the care of their children. Importantly, these disparities remained when income, insurance, level of education, and the number of parents in the household were included in multivariate analyses (Magaña, Parish, Rose, Timberlake, & Swaine, 2012). Similar analyses have supported these findings that minority children with disabilities are less likely to experience family-centered care (Coker, Rodriguez, & Flores, 2010; Magaña, Parish, & Son, 2015; Montes & Halterman, 2011).

Along with disparities for black and Hispanic families, limited data reveal that American Indian/Alaskan Native CSHCN are more likely to have a greater number of chronic conditions and functional difficulties than white CSHCN and that they are more likely to be affected in their daily activities than white CSHCN (Kenney & Thierry, 2014). Across all races, parents with limited English proficiency—defined by the U.S. Census Bureau as speaking English less than “very well”—are more likely to report that their children with disabilities

Figure 42.3. National Survey of Children with Special Health Care Needs: Receipt of family-centered care, by race/ethnicity. (From U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau. [2013]. *The National Survey of Children with Special Health Care Needs chartbook 2009–2010*. Rockville, Maryland: Author. Retrieved from <https://mchb.hrsa.gov/cshcn0910/more/pdf/nscshcn0910.pdf>)

are uninsured, have no usual source of care, experience long appointment wait times, and lack after-hours care, all of which are known barriers to accessing adequate health care (Eneriz-Wierner, Sanders, Barr, & Mendoza, 2014; Winitzer, Bisgaier, Grogan, & Rhodes, 2012). Lack of knowledge about the complex U.S. health care system, including the process of specialty referrals and appointments, compounds this problem for immigrant families (Winitzer et al., 2012). In addition, the majority of states place limitations on publicly funded health insurance for noncitizen immigrants, and fear of exposing their undocumented status may also cause immigrant families to avoid accessing needed health care.

RACIAL AND ETHNIC DISPARITIES IN SPECIAL EDUCATION

Health care is not the only area where there are ethnic and racial disparities; it also occurs in education. Thus, it is critical for educators across the spectrum from early education and beyond to recognize and address disparities. All ethnicities are not proportionally represented among students with developmental disabilities. One of the goals of the Individuals with Disabilities Education Improvement Act (IDEA) of 2004 was to reduce the overrepresentation of minorities in special education.

Figure 42.4. National Survey of Children with Special Health Care Needs: Impact of children's conditions on their daily activities, by race/ethnicity and primary language. (From U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau. [2013]. *The National Survey of Children with Special Health Care Needs chartbook 2009–2010*. Rockville, Maryland: Author. Retrieved from <https://mchb.hrsa.gov/cshcn0910/more/pdf/nscshcn0910.pdf>)

Figure 42.5. National Survey of Children with Special Health Care Needs: Annual out-of-pocket expenses for care of CSHCN, by race/ethnicity. (From U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau. [2013]. *The National Survey of Children with Special Health Care Needs chartbook 2009–2010*. Rockville, Maryland: Author. Retrieved from <https://mchb.hrsa.gov/cshcn0910/more/pdf/nscshcn0910.pdf>)

While reduction of the number of minorities in special education remains a goal of the federal government, a more recent analysis has indicated that discrimination of minorities is through both overrepresentation and underrepresentation (U.S. Department of Education, 2016). For example, school staff may overrefer students of color for potential emotional disturbance based on racial stereotypes of violent tendencies or underrefer students for a potential learning disability based on racial stereotypes of lack of motivation among students of color. English language learner students also may be underreferred for evaluation based on a belief that it would not be possible to appropriately evaluate a child who is not proficient in English. Conversely, they may be overidentified due to low performance on assessment measures resulting from the use of inappropriate assessment tools or because of misinterpretation of assessment measures (U.S. Department of Education, National Center for Education and Statistics, 2016). Recent research suggests that underachieving minority students with similar levels of socioeconomic risk factors as their white counterparts (e.g., low birth weight, adolescent mothers, poverty, lead exposure, and inadequate health insurance) are less likely to be identified with a disability and provided with appropriate special education services (Morgan et al., 2015; Morgan & Farkas, 2016; Morgan et al., 2017).

Although black students may be underidentified when compared with similar white students, black students as a group continue to have higher rates of identification than would be expected given their proportion in the general population. However, the gap is narrowing somewhat. In 2008, black students made up 31% of the population with intellectual disability in public schools and 29% of the population with emotional disturbance although they represented only 17% of the overall population. In 2014, they made up 26% of students with intellectual disability and 25% of students with emotional disturbance while representing 18% of total student enrollment (U.S. Department of Education, Office of Special Education and Rehabilitative Services, 2016).

Contrary to common perception, the rate of overrepresentation in special education increases as free lunch status decreases. Black students are more likely to be overidentified in wealthy districts than in districts of poverty. Teachers' classroom management skills, unintentional bias toward the student (including the use of less positive interactions), impressions of families, informal diagnosis of a learning disability or attention-deficit/hyperactivity disorder, external pressure for identification and placement, percentage of minority teachers, student-teacher ratios, and adequate levels of school funding are all contributing factors to

overdiagnosis (de Valenzuela, Copeland, Huaqing Qi, & Park, 2006; Skiba, Poloni-Staudinger, Gallini, Simmons, & Feggins-Azziz, 2006; Tenenbaum & Ruck, 2007; van den Bergh, Denessen, Hornstra, Voeten, & Holland, 2010).

Overrepresentation also exists in the area of discipline in school. Both black and Hispanic students are more likely to be suspended than their white classmates. In elementary school, black students are 2.2 times more likely to be suspended than white students; in middle school, that likelihood increases to 3.8 times. Hispanic middle school students are 1.7 times more likely to be suspended (Skiba, Shure, & Williams, 2012). More recent data suggest that black students as a whole are nearly four times more likely to be suspended than white students (U.S. Department of Education, Office for Civil Rights, 2016). Students of color are also disproportionately more likely to be expelled from school regardless of socioeconomic status. In fact, the higher the socioeconomic status of the district, the higher the rates of suspension among students of color (American Psychological Association Zero Tolerance Task Force, 2008; Skiba et al., 2012). This overrepresentation is important because students suspended or expelled are three times more likely than other students to be involved with the juvenile justice system in the next year (The Council of State Governments, 2011).

■ ■ ■ CASE STUDY

Shontell is a 5-year-old black girl starting kindergarten at a public school. Her teacher, Mrs. Singh, notices that Shontell walks on her toes, has difficulty going up and down stairs, and falls often, especially on the playground. She learned from Shontell's mother, Jasmine, that Shontell was born prematurely. Jasmine worries that Shontell may have cerebral palsy. Due to financial hardships the family has not had stable housing and has had to move often, staying with different friends and family members. Jasmine works whenever she can to support the family, and medical visits take several hours when commuting on public transportation. As a result, Shontell has not had consistent appointments with the same pediatrician, and no official diagnosis has been made. Mrs. Singh shares with Jasmine the availability of school therapy services and the process of beginning an individualized education program (IEP) evaluation. Within the next 60 days, a physical therapist employed by the county school program visits the classroom to evaluate Shontell's balance and strength with functional activities needed to move about the classroom safely and independently. The school team completes the IEP process in partnership with Jasmine, and Shontell begins to receive the recommended in-school services.

ETIOLOGIES AND FEDERAL INITIATIVES

Racial and ethnic health and educational disparities exist among children with disabilities, and the barriers to health and education equity are multifactorial. According to a model developed by Kilbourne and colleagues (Figure 42.6), key potential determinants of health disparities include individual, provider, and health care system factors (Kilbourne, Switzer, Hyman, Crowley-Matoka, & Fine, 2005). In this model, individual (patient)-level factors include race, ethnicity, culture, beliefs, preferences, education and resources, and biologic or genetic factors. Health care provider-level factors include knowledge and attitudes, competing demands, and bias. Providers and educators, in particular, may be vulnerable to unconscious processes such as bias or stereotyping. In the health care field, this, in turn, can adversely impact the clinical encounter, as provider communication and **cultural competence** are additional factors that can contribute to health disparities, as detailed in the Considerations for Clinicians section of this chapter.

Finally, there are structural- and institutional-level factors relating to the health care system that include health services organizations, financing, and delivery as well as health care organization culture and quality improvement (Kilbourne et al., 2005). Institutionalized racism is increasingly recognized as a key factor

in the development of health disparities in the United States. Institutionalized racism is defined as “differential access to the goods, services, and opportunities of society by race” and is differentiated from personally mediated prejudice or racism. Institutionalized racism is reflected in norms and laws that have led to discrepancies in access to material conditions and power for certain racial groups over time and is perpetuated in modern-day social structures (Jones, 2000, p. 1212). A history of inequality in access to education, voting rights, housing, and employment contributes to the socioeconomic disparities among races in the United States today. For families struggling with the care of a child with disabilities, multigenerational difficulties due to codified racial discrimination add to the barriers to accessing health care and special education services and feeling empowered through the care process.

Federal policies that support children and families with disabilities—including IDEA 2004, the Americans with Disabilities Act, and Section 504 of the Rehabilitation Act of 1973—aim to reduce these impediments to health care access and to decrease disparities (see Chapter 33). These laws mandate public schools to accommodate or find alternate accommodations for every child with a disability. A child who enters the public school system and has a known or suspected disability would undergo an evaluation to determine placement in special education services, as illustrated

Figure 42.6. Kilbourne model Venn diagram. (From Kilbourne AM, Switzer G, Hyman K, Crowley-Matoka M, and Fine MJ. Advancing Health Disparities Research Within the Health Care System: A Conceptual Framework. *Am J Public Health*. 2006 December; 96[12]: 2113–2121; reprinted by permission.)

in Shontell's case. In addition, the reauthorization of the IDEA in 2004 specified a goal to reduce the overrepresentation of black youth in special education, particularly in the domains of intellectual disability and emotional disturbance (U.S. Department of Education, National Center for Education Evaluation and Regional Assistance, Institute of Education Sciences, 2011). These federal policies underscore the critical role that individual educators and school systems as a whole can play in reducing disparities. As children typically spend a significant amount of their waking hours in school, learning, emotional, and physical disabilities may be first identified and managed within the school system; this is of particular importance for children who may have limited access to the health care system.

■ ■ ■ CASE STUDY

Julia is a white occupational therapy student in her first clinical fieldwork placement. She is working in acute care at a large urban children's hospital evaluating and treating children with chronic illness, cancer, and traumatic injury. One day she and her clinical instructor evaluate a child who was severely abused and burned by his father. Afterwards, Julia expresses to her clinical instructor that she is surprised that the child is white. The clinical instructor explains to Julia the concept of **implicit bias** and how assuming the child would be of a minority race implies that people of color are more likely to commit child abuse. He introduces her to an online implicit association test (IAT), which helps her to assess and identify unconscious negative thoughts she holds toward people of color. Through this process, Julia becomes more self-aware and able to recognize ways that she is allowing stereotypes and racial bias to shape her thinking and expectations related to patient care. Because Julia is committed to excellent patient care, she has sought out additional reading and experiences to improve her cultural competence and ability to recognize her own implicit bias.

REDUCING DISPARITIES: CONSIDERATIONS FOR CLINICIANS AND EDUCATORS

The importance of clinician and educator cultural competence cannot be overstated. Skills in cultural competence (knowledge of the norms of other cultures and how to partner with families of various backgrounds), cultural humility (identifying one's own biases and seeking personal growth), and cultural agility (the ability to work effectively across cultures) are all critical for the care and education of diverse populations. These terms are distinguished by nuances, and each has

value in various contexts. This chapter uses the term *cultural competence*, which is more commonly used in published studies, and defines it as the skill needed to partner effectively across various cultures while recognizing one's own explicit and implicit biases.

When contemplating how to address health and educational disparities in children with special needs, the Kilbourne model of potential sources of disparities can be helpful. This model addresses patient-level, provider-level, clinical encounter, and health care system factors that contribute to disparities in care (Kilbourne et al., 2005). When extending this model to education and children with disabilities, factors resulting in disparities of care among this vulnerable population include attitudes of health care providers, educators, and the public; physical barriers; miscommunications; income level; ethnic/minority status; insurance coverage; and lack of information tailored to people with disabilities (Sharby et al., 2015). Understanding the factors that contribute to health and educational disparities can inform interventions to achieve health and education equity.

Clinician and educator knowledge and attitudes can contribute to the delivery of unequitable health care and education. Patients cite that providers often lack the necessary time, clinical training, equipment, and resources to provide adequate care for their complex medical needs (Morrison, George, & Mosqueda, 2008). Clinical competency centered on the care of children with disabilities is often inadequate. For instance, when medical students underwent assessments regarding examination skills, they demonstrated significantly more difficulty in both interpersonal skills and physical examination skills when the patient had a disability (Brown, Graham, Richeson, Wu, & McDermott, 2010). However, studies have shown that with increased education, clinician knowledge and attitudes can be modified (Moroz et al., 2010; Symons, Morley, McGuigan, & Akl, 2014). Therefore, the development of curricula for medical schools, programs for other health professionals, and schools of education that focus on increasing the quality of care provided to children with disabilities, particularly regarding communication skills and clinical knowledge, is of paramount importance.

The families of children with disabilities have reported difficulty concentrating on and understanding what their clinician or educator is stating. This barrier may arise especially in cases of intellectual disabilities, hearing impairments, and communication disorders, and it may be further compounded if the clinician or educator is not communicating in a family's native language (O'Day, Killeen, Sutton, & Iezzoni, 2005) or if the recommendations are incompatible with a family's cultural background or socioeconomic status.

If the children and their families believe that clinicians or teachers do not understand them or are uninterested in learning about them and their culture, strengths, and challenges, they will be less likely to seek or continue care, to be open and honest in their communication, and to follow through with recommendations. For instance, the NS-CSHCN demonstrated an association of delayed or foregone care and dissatisfaction with care with parents' perceptions of health care providers' cultural competence (Kerfeld, Hoffman, Ciol, & Kartin, 2011). Health care providers should focus on developing a constructive relationship with the child and his or her family by encouraging them to ask questions and by demonstrating genuine interest in their lives, empathy, and concern for their health. Providing these elements of family-centered care may reduce disparities in health care utilization among minority children with disabilities (Parish, Magaña, Rose, Timberlake, & Swaine, 2012; Box 42.1). Similar approaches can be helpful in the school environment.

Furthermore, clinicians and educators should deliver care recommendations or details of an IEP in a manner that is understandable to children and their families and seek a confirmation of understanding. However, while clinicians or teachers can choose to learn a few key phrases such as "hello" and "thank you" in the languages spoken by one's patients/students to increase rapport, their language skills should be tested and certified before communicating more

intensively in those languages (White & Stubblefield-Tave, 2017). Qualified interpreter services should be used with families who have limited English proficiency. It is also important to be sensitive to a family's health and educational literacy, and it may be necessary to provide supplemental materials such as pictures, videos, or low-literacy handouts to the family to promote understanding. Conducting a teach-back, during which the child and his/her family state in their own words the health or educational issues and steps to address the problem at the conclusion of a visit or IEP meeting will help demonstrate whether the clinician/teacher effectively communicated the issues. This represents best practice for communication of health information (White & Stubblefield-Tave, 2017).

Bias in medicine has been previously demonstrated. The Institute of Medicine (now the National Academy of Medicine) has concluded that some evidence suggests that "bias, stereotyping, prejudice, and clinical uncertainty on the part of healthcare providers may be contributory factors to racial and ethnic disparities in healthcare" (Institute of Medicine, 2003, p. 178). Although overt (explicit) discriminatory laws and practices in the United States may have declined in recent decades, covert discrimination and institutional bias are sustained by subtle, implicit (unconscious) attitudes that may influence provider behavior and treatment choices (Hall et al., 2015). As a result, compared with white patients, minority patients may be kept waiting

BOX 42.1 EVIDENCE-BASED PRACTICE

Family-Centered Care

Family-centered care is an evidence-based approach to health care that recognizes that "a partnership among patients, families, and health care professionals is essential to providing quality care" (Coker et al., 2010, p. 1160). As defined by the American Academy of Pediatrics (2003), family-centered care is grounded in a core set of principles, including but not limited to the following:

- Honoring racial, ethnic, cultural, and socioeconomic diversity and its effect on the family's experience and perception of care
- Supporting and facilitating choice for the child and family about approaches to care and support
- Ensuring flexibility in organizational policies, procedures, and provider practices so services can be tailored to the needs, beliefs, and cultural values of each child and family
- Collaborating with families at all levels of health care in the care of the individual child and in professional education, policy making, and program development

Evidence has shown that providing family-centered care in the pediatric setting improves patient outcomes, including reduced patient and parent anxiety, shortens postsurgical recovery times, and increases parents' confidence and problem-solving capacity. In addition, staff in family-centered environments are more likely to provide culturally competent care, report more positive feelings about their patients and their work, and have a lower risk of malpractice lawsuits (American Academy of Pediatrics, 2003; Coker et al., 2010; Magaña et al., 2015).

longer for treatment, may end up having a provider spend less time with them, may be spoken to by providers with a more condescending tone, may receive different treatment plans based on assumptions about adherence capabilities, and so forth (Hall et al., 2015). Some of these same issues exist in the school environment, where the teacher may spend less time with minority parents in conferences or be less positive in their description of the child's performance or behavior.

Tools such as the online IAT (Project Implicit, 2017) provide a validated measure of our implicit biases because they test associative processes that operate automatically and thus are resistant to "faking" or social desirability bias (Dehon et al., 2017). A study of primary care visits examined the relationship between clinician implicit racial bias scores with visit communication through recorded visits and patient ratings of care. In comparison with white patients, when caring for black patients, clinicians with a pro-white bias were more likely to keep patients waiting longer, communicate with verbal dominance, be perceived as less patient centered, and receive poorer ratings of interpersonal care (Cooper et al., 2012). Even well-meaning trainees are not immune to bias. In one study, the vast majority of resident physicians working in an urban pediatric emergency department exhibited pro-white/anti-black racial bias on the child race IAT regardless of their own race, gender, or specialty (Johnson et al., 2017). Unconscious racial bias has also been documented among teachers, with potential effects on student achievement and discipline (Neal, McCray, Webb-Johnson, & Bridgest, 2003; van den Bergh et al., 2010). The IAT has multiple tests regarding race, ethnicity, disability, and many others and is recommended for trainees, practitioners, and educators seeking to examine their own potential biases. The IAT is publicly available at <https://implicit.harvard.edu>.

Acknowledging biases, both explicit and implicit, is critical to providing equitable care and education. Once providers are able to recognize their own biases, reducing them involves 1) training providers to understand the psychological basis of bias, 2) increasing their internal motivation to address bias in a nonthreatening environment, 3) improving their emotional regulation skills specific to positive interactions, and 4) enhancing providers' self-efficacy in interactions with racially or socially dissimilar patients (Burgess, van Ryn, Dovidio, & Saha, 2007). Along with addressing these unconscious processes, successful training also includes building skills to effectively communicate and negotiate across cultures, languages, and literacy levels (Dykes & White, 2009; Smith et al., 2007). Racial disparities in education can similarly be tempered through

interventions such as teacher education in cultural competence; multitiered systems of support, including positive behavioral interventions and supports; and response to intervention (see Chapter 33; Fenning & Sharkey, 2012). These interventions are designed to systematically identify student needs and to provide individualized, high-quality instruction to maximize positive student outcomes.

Finally, clinicians and educators should advocate for institutional and national policies that address disparities and promote equity, including holding their institutions and places of employment accountable for providing culturally and linguistically competent care and education, along with training in cultural competence. This may also involve advocating that a health care institution or school include cultural or racial group analyses and responses to feedback surveys and health/education outcomes data (White & Stubblefield-Tave, 2017). In addition, hiring practices can influence patient-provider and student-teacher rapport, as diversity on clinical and educational teams can reduce unintentional cultural insensitivity (Dykes & White, 2009). Specifically for children with disabilities, employing linguistically competent care coordinators can increase parent satisfaction with care given within the medical home (Hamilton, Lerner, Presson, & Klitzner, 2013). Cultural competence is not only an individual pursuit—it also requires institutional changes in practice. Further research into how federal and state health care financing affects utilization in children with disabilities will be needed to inform legislative advocacy efforts (see Chapter 41).

SUMMARY

- Families with children with disabilities face challenges with accessing quality health care and education, with even greater difficulties reported by racial and ethnic minorities.
- The origins of these disparities are multifactorial, and their effects on health and educational outcomes are an ongoing subject of research, but it is becoming increasingly clear that clinicians and educators can contribute to both raising and reducing barriers to equitable and culturally competent care.
- An initial step toward reducing health and educational disparities is clinician/teacher self-assessment of bias utilizing a tool such as the IAT and bringing these unconscious processes to light.
- Organizational training and ensuring diversity in teams are components of institutional changes that are critical for enhancing cultural competence.

- Ongoing research is needed to track both disability-related and racial/ethnic disparities in order to determine the best practices on the individual, organizational, and national levels that lead to reductions in disparities for the highly vulnerable population of children with disabilities.

APPENDIX **A**

Glossary

AAC See augmentative and alternate communication.

ABA See applied behavior analysis.

abducens nerve The sixth nerve; controls the lateral rectus eye muscle.

abducted Part of the body moved away from the midline.

abduction Moving part of the body away from one's midline.

ABR See auditory brainstem response.

abruptio placenta Premature detachment of a normally situated placenta; *also called* placental abruption.

abscesses Localized collections of pus in cavities caused by the disintegration of tissue, usually the result of bacterial infections.

accommodation 1) In special education, a change in how a student gains access to the curriculum or demonstrates his or her learning. This approach does not substantially alter the content or level of instruction (e.g., allowing a student additional time to take a test); 2) the change in the shape of the lens of the eye that allows it to focus on objects at varying distances.

acetabulum The cup-shaped cavity of the hip bone that holds the head of the femur in place, creating a joint.

acetylcholine A neurotransmitter for cholinergic neurons that innervate many tissues, including smooth muscle and skeletal muscle.

acetylcholinesterase (ACHE) An enzyme that stops excitation of a nerve after transmission of an impulse.

acid-base balance In metabolism, the ratio of acidic to basic compounds (or pH).

acidosis Abnormally high levels of acid in the bloodstream. The normal pH is 7.42; acidosis is generally less than pH 7.30.

acquired immunodeficiency syndrome (AIDS) Severe immune deficiency disease caused by human immunodeficiency virus (HIV).

actin Protein involved in muscle contraction.

acute inflammatory peripheral neuropathy The most common form is Guillain-Barre syndrome. It involves an ascending paralysis, with weakness beginning in the feet and hands and migrating toward the trunk. It can cause life-threatening complications, particularly if the breathing muscles are affected or if there is dysfunction of the autonomic nervous system. The disease is usually triggered by an acute infection.

adaptive skills The skills necessary to effectively and independently take care of oneself.

adaptive technology Substitutes or makes up for the loss of function brought on by a disability (e.g., software that permits voice production through a computer for an individual who cannot speak).

adduction Moving a body part, usually a limb, toward the midline.

adenine One of the four nucleotides (chemicals) that comprise DNA.

adenoid Lymphatic tissue located behind the nasal passages.

adenoidectomy The surgical removal of the adenoids.

adenoma sebaceum Benign cutaneous growths, usually seen around the nose, that resemble acne; these occur in individuals with tuberous sclerosis (*see* Appendix B).

adenotonsillectomy Surgical removal of adenoids and tonsils.

adherence Compliance.

adjustment disorders A group of psychiatric disorders, usually of childhood, associated with difficulty adjusting to life changes.

adrenaline A potent stimulant of the autonomic nervous system. It increases blood pressure and heart rate and stimulates other physiological changes needed for a "fight-or-flight" response.

advance directives In children with severe disabilities or diseases, the term is used to define the level of

intervention a parent wants provided in the event of life-threatening emergency or illness in the child.

adverse drug reactions (ADRs) Harmful reaction experienced following the administration of a drug or combination of drugs given at normal doses.

AED See automated external defibrillator.

afferent Pertaining to the neural signals sent from the peripheral nervous system to the central nervous system (CNS). Sensory fibers carry signals from muscles, skin, and joints back to the brain.

AFO See ankle-foot orthosis.

AFP See alpha-fetoprotein.

afterbirth See placenta.

agenesis of the corpus callosum Absence of the band of white matter that normally connects the two hemispheres of the brain.

agonist A muscle that works in concert with another muscle to produce movement.

agyria Absence of the normal convolutions on the surface of the brain.

AIDS See acquired immunodeficiency syndrome.

alcohol-related neurodevelopmental disorder (ARND) *Previously called fetal alcohol effects (FAE); refers to the range of neurological and developmental impairments that can affect a child who has been exposed *in utero* to alcohol. The most severe of these effects is fetal alcohol syndrome.*

alleles Alternate forms of a gene that may exist at the same site on the chromosome.

alopecia The partial or complete absence of hair from areas of the body where it normally grows.

alpha-fetoprotein (AFP) Fetal protein found in amniotic fluid and serum of pregnant women. Its measurement is used to test for meningomyelocele and Down syndrome in the fetus and is a chemical typically found in the fetal spinal fluid, brain, and spinal cord.

alternative technology See adaptive technology.

alveoli Small air sacs in the lungs. Carbon dioxide and oxygen are exchanged through their walls.

amalgam An alloy of mercury and silver used in dental fillings.

amaurosis Blindness with no change in the eye but due to disease of brain, nerve, or spinal cord.

amblyopia Partial loss of sight resulting from disuse atrophy of neural circuitry during a critical period of development, most often associated with untreated strabismus in children.

amino acid Building block of protein needed for normal growth.

amino acid disorders Inborn errors of metabolism resulting from an enzyme deficiency involving amino acids, the building blocks of protein.

amniocentesis A prenatal diagnostic procedure performed in the second trimester in which amniotic fluid is removed by a needle inserted through the abdominal wall and into the uterine cavity.

amniotic fluid Clear fluid that surrounds the fetus during pregnancy, acting as a physical buffer for fetal

movements and physical development. It is formed by fetal urine production and lung fluid secretion during fetal respirations.

amygdala A part of the brain involved in sensory procession and emotions.

anaphase The stage in cell division (mitosis and meiosis) when the chromosomes move from the center of the nucleus toward the poles of the cell.

anaphylaxis A life-threatening hypersensitivity response to a medication or food, marked by breathing difficulty, hives, and shock.

anemia Disorder in which the blood has either too few red blood cells or too little hemoglobin.

anencephaly Neural tube defect (NTD) in which either the entire brain or all but the most primitive regions of the brain are missing.

aneuploidy Abnormal number of chromosomes in a cell, for example a human cell having 45 or 47 chromosomes instead of the usual 46.

angiogenesis Development of new blood vessels.

angular cheilitis Inflammation starting at the angles of the mouth and affecting the lips. It is usually caused by nutritional deficiencies, atopic dermatitis, or yeast infection.

ankle-foot orthosis (AFO) An appliance or brace that stabilizes the position of the foot and provides a consistent stretch to the Achilles' tendon.

anodontia The congenital absence of all primary or permanent teeth.

anomalies Birth defects caused by structural abnormalities.

anophthalmia Congenital absence of the eye globes.

anorexia A severe loss of appetite.

anotia Congenital absence of the external ear (auricle).

antagonists Muscles that work at cross-purposes (e.g., the adductor and abductor muscles of the hip oppose each others' actions).

antecedents Events or contextual factors that precede the manifestation of a behavior.

anterior The front part of a structure.

anterior chamber The space between the cornea and lens of the eye.

anterior fontanelle The membrane-covered area on the top of the head; *also called* the "soft spot." It generally closes by 18 months of age.

anterior horn cells Cells in the spinal column that transmit impulses from the pyramidal tract to the peripheral nervous system.

anthropometrics Measurements of the body and its parts.

antibody A protein formed in the bloodstream to fight infection.

anticholinergic medications A group of medications that acts by antagonizing the effects of the neurotransmitter acetylcholine.

anticipation A term used in genetics to denote an expansion in triplet repeats from one generation to the next, leading to a more severe manifestation of the disease (e.g., in fragile X syndrome).

anticonvulsants Medications used for control of seizures.

- antidepressants** Medications used to control major depression.
- antigen** A substance that, when introduced into the body, triggers the production of an antibody by the immune system, which will then kill or neutralize the antigen that is recognized as a foreign and potentially harmful invader.
- antihistamine** A drug that counteracts the effects of histamines, substances involved in allergic reactions.
- antipsychotic medications** Medications used to treat psychosis; the atypical antipsychotics have also been found to be useful in treating aggression and self-injury in children with severe intellectual disability.
- antipyretics** Medications used to treat fever.
- antiretroviral agents (ARVs)** A category of medications used to treat retroviral infections (i.e., HIV/AIDS).
- anuria** In chronic renal (kidney) failure, the absence of urine production.
- anxiety disorders** Psychiatric disorders characterized by feelings of anxiety. The disorders include panic attacks, separation anxiety, social anxiety, obsessive-compulsive disorder (OCD), and posttraumatic stress disorder (PTSD).
- aorta** The major artery, originating in the left ventricle of the heart and supplying oxygenated blood to the body and brain.
- Apgar scoring system** Scoring system developed by Virginia Apgar to assess neurological status in the newborn infant. Scores range from 0 to 10.
- aphasia** A class of language disorder that ranges from having difficulty remembering words to being completely unable to speak, read, or write due to damage to the brain.
- apical** At the tip of a structure.
- apnea** A lack of spontaneous breathing effort; brief breathing arrests.
- apneic** Pertaining to an episodic arrest of breathing.
- apoptosis** Programmed cell death.
- applied behavior analysis (ABA)** A treatment method, commonly used in autism, that uses behavioral learning theory to change behavior.
- appropriate-for-gestational-age** The term used when the baby's gestational age findings (e.g., length and weight) after birth match the baby's calendar age.
- apraxia** The inability to perform coordinated movements or manipulate objects in the absence of a motor or sensory impairment.
- aqueous humor** The watery fluid in the eyeball that fills the anterior chamber (the space between the lens and the cornea).
- arborization** A process during neuronal differentiation by which primitive neurons begin to express their distinctive physical and biochemical features.
- arachnoid granulations** The small whitish villi of the arachnoid membrane, the middle of the three membranes or meninges that surround the brain and spinal cord.
- architectonic dysplasias** Developmental malformations affecting the neuronal architecture of the brain.
- areflexia** Lack of deep tendon reflexes.
- ARFID** See avoidant/restrictive food intake disorder.
- ARND** See alcohol-related neurodevelopmental disorder.
- arterial blood gas** A laboratory profile test of sampled arterial blood, including pH, PaO₂, and PaCO₂.
- arterial-venous malformation (AVM)** Birth defect of blood vessels, most commonly in the brain, that can be associated with a disastrous postthrombotic hemorrhage.
- arthritis** An inflammatory disease of joints.
- arthrogryposis** Congenital condition characterized by reduced mobility of multiple joints due to contractures.
- articular** Referring to the surface of a bone at a joint space.
- articulation** 1) The formulation of individual speech sounds; 2) the connection at a joint.
- articulation disorder** A speech disorder involving difficulties in forming specific sounds.
- ARVs** See antiretroviral agents.
- ascending infections** The transfer of microbes from the maternal genital tract through the cervix and across the amniotic membranes to the fetus.
- ASD** See autism spectrum disorder.
- asphyxia** Interference with oxygenation of the blood that leads to loss of consciousness and possible brain damage.
- aspiration** Inhalation of a foreign body, usually a food particle, into the lungs.
- aspiration pneumonia** Inflammation of the lung(s) caused by inhaling a foreign body, such as food, into the lungs; an infection by the aspiration of food into the lung.
- asplenia** Nonfunctioning spleen.
- assent** Agreement to research or treatment, given by a child or minor who is too young to give legally valid informed consent.
- assisted reproductive technology (ART)** Technology to help human reproduction (e.g., *in vitro* fertilization).
- assistive** Providing assistance.
- assistive devices** Any device used to assist in a body function (e.g., a wheelchair).
- assistive technology (AT)** Technology (often software) to improve communication, movement, independence, and so forth.
- astigmatism** A condition of unequal curvature of the cornea that leads to blurred vision.
- astrocytes** Support cells in the central nervous system (CNS) that help form the white matter.
- asymmetrical tonic neck reflex (ATNR)** A primitive reflex, *also called* the fencer's response, found in infants; usually is no longer evident by 3 months of age. When the neck is turned in one direction, the arm shoots out on the same side and flexes on the opposite side; similar changes occur in the legs.
- ataxia** An unbalanced gait or movement of any part of the body caused by a disturbance of cerebellar control. Movements are jerky and uncoordinated, without the smooth flow of normal motion.
- ataxic** Erratic and uncoordinated voluntary movement.
- ataxic cerebral palsy** A form of dyskinetic cerebral palsy in which the prominent feature is ataxia; characterized

- by abnormalities of voluntary movement involving balance and position of the trunk and limbs in space (ataxia). Ataxic cerebral palsy may be associated with increased (spastic) or decreased (hypotonic) muscle tone.
- athetoid cerebral palsy** A form of dyskinetic cerebral palsy associated with athetosis.
- athetosis** Constant random, slow, writhing involuntary movements of the limbs.
- atlantoaxial instability (AAI)** Excessive movement at the junction between the atlas (C1) and axis (C2) bones in the upper spine as a result of either a bony or ligamentous abnormality. This is a common finding in Down syndrome.
- atlantoaxial subluxation** Partial dislocation of the upper spine, a particular risk in Down syndrome.
- ATNR** *See* asymmetrical tonic neck reflex.
- atonic** Pertaining to the absence of normal muscle tone.
- atopic dermatitis** Eczema.
- atresia** Congenital absence or abnormal narrowing of a body passage or opening.
- atria** The two upper chambers of the heart.
- atrial septal defect** A congenital heart defect in which there is lack of closure of the wall separating the two upper chambers of the heart.
- attention-deficit/hyperactivity disorder (ADHD)** A developmental disorder characterized by impulsivity, hyperactivity, and inattention to a degree that leads to impairment in functioning.
- attrition** The wearing away by friction or rubbing (e.g., by tooth grinding).
- atypical** Unusual.
- audiometry** A hearing test using a device called an audiometer that yields results in the form of a graph showing hearing levels in sound intensity at various wavelengths of sound presented through earphones.
- auditory agnosia** Inability to distinguish different sounds in the presence of normal hearing.
- auditory brainstem response (ABR)** A test of central nervous system hearing pathways.
- augmentative and alternative communication (AAC)** Devices that assist individuals who lack the ability to speak (e.g., a microchip-powered voice output augmentative device for a person with dysarthria).
- augmentative devices** Devices used to increase an area of functioning that is deficient, sometimes severely, but for which there are some residual abilities.
- aura** A sensation, usually visual and/or olfactory, marking the onset of a seizure.
- auricle** The outer ear.
- autism spectrum disorder (ASD)** A developmental disorder with persistent deficits in social communication and interaction as well as restrictive, repetitive patterns of behavior, interests, and activities.
- autoimmune** Pertaining to a reaction in which one's immune system attacks other parts of the body.
- automated external defibrillator (AED)** Portable electronic device that automatically diagnoses the potentially life-threatening cardiac arrhythmias of ventricular fibrillation and ventricular tachycardia in a patient and can provide an electrical impulse to correct the arrhythmia.
- automatic movement reactions** *See* postural reactions.
- automatic reinforcement** A behavior that produces internal consequences that can reinforce and thus produce functional relationships that maintain the problem behavior.
- automatisms** Automatic fine motor movements (e.g., unbuttoning one's clothing—i.e., unconscious) that are part of a seizure.
- autonomic** Describing the part of the nervous system that regulates certain automatic functions of the body (i.e., heart rate, sweating, and bowel movement).
- autonomic nervous system** Controls involuntary activities of the cardiovascular, digestive, endocrine, urinary, respiratory, and reproductive systems.
- autonomy** The ability and/or right to be self-determining; an important concept regarding participating in human trials research.
- autosomal dominant** Mendelian inheritance pattern in which a single copy of a gene (from either mother or father) leads to expression of the trait.
- autosomal recessive** Mendelian inheritance pattern in which identical copies of a gene from both mother and father are required to result in the expression of a trait.
- autosomes** The first 22 pairs of chromosomes. All chromosomes are autosomes except for the two sex chromosomes.
- avascular necrosis** Destruction of bone from microvascular occlusion.
- aversive** Pertaining to a stimulus, often unpleasant, that decreases the likelihood a particular response will subsequently occur.
- AVM** *See* arterial-venous malformation.
- avoidant/restrictive food intake disorder (ARFID)** Intake disturbance in which a child eats too little, eats a limited variety, or has fear of eating, resulting in either faltering growth, nutritional deficiency, dependence on nutritional supplements, and/or interference with psychosocial functioning.
- axon** A long, slender projection of a nerve cell, or neuron, that conducts electrical impulses away from the neuron's cell body.
- Babinski sign** Upgoing toe when the sole of the foot is stroked firmly, often a sign of cerebral palsy outside of the newborn period.
- backward chaining** Method of teaching a task in which the instructor begins by teaching the last step in a sequence because this step is most likely to be associated with a potent positive reinforcer.
- bacteremia** Spread of a bacterial organism throughout the bloodstream.
- banding** In genetics, pertaining to a series of dark and light bars that appear on chromosomes after they are stained. Each chromosome has a distinct banding pattern.
- barotrauma** Injury related to excess pressure, especially to the lungs or ears.

- basal** 1) Near the base; 2) relating to a standard or reference point (e.g., basal metabolic rate).
- basal ganglia** Brain structure at the base of the cerebral hemispheres involved in motor control, cognition, emotions, and learning.
- baseline** In behavior management, the frequency, duration, and intensity of a behavior prior to intervention.
- basilar membrane** The thin tissue barrier that extends from the bony shelf of the cochlea to the outer wall and supports the organ of Corti in the inner ear.
- behavior** Refers to any action that one person can perform and that another person can observe.
- behavior family therapy** A type of psychotherapy used to modify family function where one or more members is exhibiting behavior problems.
- benign childhood epilepsy with centrotemporal spikes (BECTS)** *Also called* benign rolandic epilepsy (BRE), it is the most common epilepsy syndrome in childhood. Most children will outgrow the syndrome by 18 years, and treatment with anti-epileptic drugs may not be required.
- benign occipital epilepsy** A hereditary form of focal epilepsy that involves the occipital lobe of the brain. It occurs during childhood and often does not require antiepileptic drug treatment.
- benign rolandic epilepsy (BRE)** *See* benign childhood epilepsy with centrotemporal spikes.
- benign sleep myoclonus of infancy** This form of sleep disorder happens between birth and 6 months and consists of myoclonic jerks that involve limbs, trunk, or the whole body. It occurs in clusters during quiet non-REM sleep and disappears during wakefulness.
- beriberi** Disease caused by a deficiency of the vitamin B1 (thiamin) and manifested as edema, heart problems, and peripheral neuropathy.
- beta-blockers** Medications (e.g., propranolol) that were initially used to control high blood pressure and have subsequently been found also to be useful in treating tremor and migraine headache.
- binge eating** An eating disorder in which there are recurrent episodes of ingesting large amounts of food during short periods of time.
- binocular vision** The focusing of both eyes on an object to provide a stereoscopic image.
- biotin** One of the B-complex vitamins needed to activate a number of important enzymatic reactions in the body.
- biotinidase deficiency** An inborn error of metabolism in which biotin is not released from proteins in the diet during digestion resulting in biotin deficiency. Symptoms include seizures, hypotonia and muscle/limb weakness, ataxia, hearing loss, optic atrophy, skin rashes, and alopecia. If left untreated, the disorder can rapidly lead to coma and death. Treatment involves biotin supplementation. *See* Appendix B.
- bipolar disorder** A psychiatric disorder manifested by cycles of mania and depression; *previously called* manic-depression.
- blastocyst** The embryonic group of cells that exists at the time of implantation.
- blastomere** A cell formed by cleavage of a fertilized egg.
- blepharitis** Inflammation of the eyelids.
- blood PaO₂** A measurement of the partial pressure of arterial oxygen (i.e., the amount of oxygen in the blood).
- blood pH** Blood acidity; normally around 7.40.
- blood poisoning** *See* sepsis.
- body mass index (BMI)** A measurement of the relative percentages of fat and muscle mass in the human body, in which weight in kilograms is divided by height in meters and the result used as an index of obesity.
- bolus** 1) A small rounded mass of food made ready by tongue and jaw movement for swallowing; 2) a single dose of a large amount of medication given to rapidly attain a therapeutic drug level.
- botulinum toxin (Botox)** 1) The neurotoxin that produces botulism (food poisoning). 2) Neurotoxin used in the treatment of neuromuscular disorders such as rigidity and spasticity.
- botulism** Poisoning by botulin toxin and manifested as muscle weakness or paralysis.
- BPD** *See* bronchopulmonary dysplasia.
- brachial plexus** Network of nerve fibers, running from the spine through the neck, the axilla (armpit region), and into the arm.
- brachialis** A muscle in the upper arm.
- brachycephaly** Tall head shape with flat back part of the skull. Short-headed shape to the skull due to premature closure of the coronal suture.
- bradycardia** Abnormal slowing of the heart rate, usually to fewer than 60 beats per minute.
- braille** A system of writing and printing for people who are blind or severely visually impaired.
- brainstem** The primitive portion of the brain that lies between the cerebrum and the spinal cord.
- brainstem release phenomena** In infancy abnormal non-epileptic motor phenomena that arise from brainstem centers as a result of the reduction of cortical inhibitory input secondary to an encephalopathy.
- branchial arches** A series of arch-like thickenings of the body wall in the pharyngeal region of the embryo.
- bronchopulmonary dysplasia (BPD)** A chronic lung disorder that occurs in a minority of premature infants who previously had respiratory distress syndrome (hyaline membrane disease). It is associated with "stiff" lungs that do not permit adequate exchange of oxygen and carbon dioxide, frequently leads to dependence on ventilator assistance for extended periods, and markedly increases the risk for the child developing asthma in the future.
- bronchospasm** Acute constriction of the bronchial tube, most commonly associated with asthma.
- bruxism** Repetitive grinding of the teeth.
- buccal** Pertaining to the cheek.
- bulging fontanel** Bulging soft spot on the crown of the head.
- bulk** Foodstuffs that increase the quantity of intestinal contents and stimulate regular bowel movements. Fruits, vegetables, and other foods containing fiber provide bulk in the diet.

- caffeine** A central nervous system (CNS) stimulant found in coffee, tea, and cola. It has been used to treat apnea and bradycardia in premature infants.
- calcify** To become hardened through the laying down of calcium salts.
- calculus** An abnormal collection of mineral salts on the tooth, predisposing it to decay; *also called* tartar; when plaque becomes calcified.
- callus** A disorganized network of bone tissue that forms around the edges of a fracture during the healing process.
- camptodactyly** Deformity of fingers or toes in which they are permanently flexed, frequently the fifth finger.
- cancellous** Referring to the lattice-like structure in long bones (e.g., the femur).
- cardinality** The number of basic members in a set.
- cardiomegaly** Enlarged heart.
- cardiopulmonary resuscitation (CPR)** An emergency procedure involving manual pumping of the chest combined with rescue breathing that is performed in an effort to preserve intact brain function until further measures are taken to restore spontaneous blood circulation and breathing in a person in cardiac arrest.
- cardiorespiratory arrest** Slowing or stopping of breathing and/or heart rate.
- cardiorespiratory monitor** A device used to monitor heart and respiratory rate.
- caries** Dental decay.
- case-control study** An observational epidemiologic study of people with a specific disease (or other outcome) of interest and a suitable control (e.g., comparison, reference) group of people without the disease.
- catalyze** To stimulate a chemical reaction via a compound that is not used up.
- cataracts** Clouding of the lenses of the eyes.
- catheterization** Use of a tube to infuse or remove fluids.
- caudal** Posterior pole of the developing embryo.
- caudal agenesis** A condition in which there is underdevelopment and fusion of the lower limbs. It is also associated with pelvic and base of the spine anomalies.
- caudal regression syndrome** Defects that may occur during embryonic life that can result in major malformations of the lower vertebrae, pelvis, and spine.
- caudate nucleus** Located within the basal ganglia, it is an important part of the brain's learning and memory system.
- CBF** *See* cerebral blood flow.
- cecostomy** Surgical formation of a permanent artificial opening into the cecum, the end of the colon.
- celiac disease** Congenital malabsorption syndrome that leads to the inability to gain weight and the passage of loose, foul-smelling stools. It is caused by intolerance of cereal products that contain gluten (e.g., wheat). Affected individuals should avoid wheat and other grains.
- central hypoventilation** Shallow breathing leading to low oxygen level resulting from disordered cerebral control of respiration.
- central nervous system (CNS)** The portion of the nervous system that consists of the brain and spinal cord. It is primarily involved in voluntary movement and thought processes.
- central venous line** A catheter that is advanced through a peripheral vein to a position directly above the opening to the right atrium of the heart. It is used to infuse long-term medication and/or nutrition.
- centrioles** Tiny organelles that migrate to the opposite poles of a cell during cell division and align the spindles.
- centromere** The constricted area of the chromosome that usually marks the point of attachment of the sister chromatids to the spindle during cell division.
- cephalocaudal** From head to tail; refers to neurological development that proceeds from the head downward.
- cephalohematoma** A swelling of the head resulting from bleeding of scalp veins. Often found in newborn infants; it is usually not harmful.
- cerebellum** A cauliflower-shaped brain structure located just above the brainstem beneath the occipital lobes at the base of the skull that is principally involved in muscle tone and coordination of movement. It may also be involved in some cognitive functions such as attention and language as well as in regulating fear and pleasure responses.
- cerebral blood flow (CBF)** Autoregulated blood flow in the brain.
- cerebellar cognitive affective syndrome** A syndrome associated with cerebellar injury that includes a combination of impairment of executive functions such as planning, set-shifting, verbal fluency, abstract reasoning, and working memory; difficulties with spatial cognition, including visual-spatial organization and memory; and personality change with blunting of affect or disinhibited and inappropriate behavior.
- cerebral contusion** A bruise on the cerebral hemispheres.
- cerebral hemisphere** Either of the two halves of brain substance.
- cerebral palsy** A disorder of movement and posture due to a nonprogressive defect of the immature brain. *See* Chapter 21.
- cerebral vascular accident (CVA)** A thrombotic (clot) or hemorrhagic (bleed) stroke that can damage large regions of the brain in the location of a particular blood vessel (artery or vein).
- cerebrospinal fluid (CSF)** Clear, watery fluid that fills the ventricular cavities within the brain and circulates around the brain and spinal cord.
- cerumen** Ear wax.
- cervical** Pertaining 1) to the cervix or 2) to the neck.
- cesarean section (C-section)** A surgical operation for delivering a baby through incising the uterus.
- Charcot-Marie-Tooth disease (CMT)** One of the hereditary motor and sensory neuropathies, a group of varied inherited disorders of the peripheral nervous system characterized by progressive loss of muscle tissue and touch sensation across various parts of the body. *See* Chapter 9 and Appendix B.
- CHARGE syndrome** A syndrome defined by coloboma of the eye, heart defects, atresia of the choanae,

- retardation of growth and/or development, genital and/or urinary abnormalities, and ear abnormalities and deafness. These children may have significant vision and hearing impairments. *See* Appendix B.
- cheilitis** An inflammation of the lips.
- chelation therapy** The use of an oral, intravenous, or topical medication to remove metal from the body, most commonly used in lead poisoning.
- chemotaxis** The phenomenon in which cells direct their movements according to certain chemicals in their environment. This is critical to early development (e.g., movement of sperm toward the egg during fertilization) and subsequent phases of development (e.g., migration of neurons or lymphocytes) as well as in normal cellular function.
- chemotherapy** Drugs used to treat cancer.
- chest physiotherapy (CPT)** A general term referring to treatments generally performed by respiratory therapists to improve breathing by the indirect removal of mucus from the breathing passages.
- Chiari malformation** A congenital defect characterized by the downward displacement of the cerebellum through the opening at the base of the skull.
- Chiari type II malformation** An abnormality, wherein the brainstem and part of the cerebellum are displaced downward toward the neck, rather than remaining within the skull.
- childhood apraxia of speech (CAS)** A pediatric speech sound disorder in which the precision and consistency of movements underlying speech are impaired in the absence of evident neuromuscular deficits.
- choanal atresia** Congenital closure of the nasal passage; part of the CHARGE association.
- cholelithiasis** Gall stones.
- cholesteatoma** A complication of otitis media in which skin cells from the ear canal migrate through the perforated eardrum into the middle ear, or mastoid region, forming a mass that must be removed surgically.
- chorea** A disorder marked by involuntary jerky movements of the extremities.
- choreoathetosis** Movement disorder, characteristic of dyskinetic cerebral palsy, involving frequent involuntary spasms of the limbs; when chorea and athetosis are seen together.
- chorioamnionitis** An infection of the amniotic sac that surrounds and contains the fetus and amniotic fluid.
- chorion** The outermost covering of the membrane surrounding the fetus.
- chorionic villi** Tiny projections that sprout from the chorion to give a maximum area of contact with the maternal blood. Embryonic blood is carried to the villi by the branches of the umbilical arteries and, after circulating through the capillaries of the villi, is returned to the embryo by the umbilical veins. The villi are part of the border between maternal and fetal blood during pregnancy.
- chorionic villus sampling (CVS)** A prenatal diagnostic procedure done in the first trimester of pregnancy to obtain fetal cells for genetic analysis; minute biopsy of the chorion.
- chorioretinitis** An inflammation of the retina and choroid that produces severe visual loss.
- choroid** The middle layer of the eyeball between the sclera and the retina.
- choroid plexus** Cells that line the walls of the ventricles of the brain and produce cerebrospinal fluid.
- chromatids** Term given to chromosomes during cell division.
- chromosomal microarray analysis (CMA)** A genetic test that can detect extra or missing segments of genetic material or DNA.
- chromosomes** Threadlike strands of DNA and associated proteins in the nucleus of cells that carry the genes transmitting hereditary information.
- CI** *See* cochlear implant.
- ciliary body** Located behind the iris, this structure allows drainage out of the eye in the angle where the cornea meets the iris through a spongelike meshwork to Schlemm's canal.
- ciliary muscles** Small muscles that affect the shape of the lens of the eye, permitting accommodation.
- circle of support** A group of volunteer advocates, such as family members, friends, and neighbors, who make sure that an individual with a developmental disability has a support system that meets all of his or her needs.
- CK** *See* creatine kinase.
- cleft** Term used in reference to a congenital deformity of the lip or palate.
- clinical cerebellar cognitive affective syndrome** A group of abnormal findings including deficits in spatial processing, working memory, and language associated with cerebellar lesions.
- clonus** Alternate muscle contraction and relaxation in rapid succession.
- clonic** Related to clonus.
- clubfoot** A congenital foot deformity; *also called* talipes equinovarus.
- CMV** *See* cytomegalovirus.
- CNS** *See* central nervous system.
- coagulation** Blood clotting.
- coagulopathy** Bleeding disorder.
- coarctation** A congenital narrowing, such as of a blood vessel, most commonly of the aorta.
- cochlea** The snail-shaped structure in the inner ear containing the hearing organ.
- cochlear amplification** The positive feedback mechanism within the cochlea involving the outer hair cell that increases the amplitude and frequency selectivity of sound vibrations using electromechanical feedback.
- cochlear implant (CI)** A device surgically implanted in the cochlea of the ear that permits a form of hearing in individuals with deafness.
- codons** Triplets of nucleotides that form the DNA code.
- cognitive strategy instruction (CSI)** CSI teaches metacognitive strategies (thinking about thinking) to improve

- learning and performance. It is beneficial when teaching more complex material involving problem solving and decision making.
- cognitive-behavioral therapy (CBT)** A type of psychotherapy that focuses on feelings about behavior.
- cohort study** An epidemiologic study of subgroups of a population identified with some common characteristic (e.g., an exposure, an ethnic background) that are followed or traced over a period of time for the occurrence of disease.
- colic** A condition in infancy marked by uncontrollable crying usually caused by abdominal discomfort and often the result of gastroesophageal reflux (GER).
- coloboma** Congenital cleft in the retina, iris, or other ocular structure.
- comorbid** A coexisting condition that worsens an underlying disorder.
- competent** Legally recognized to be able to make decisions for oneself. Minors are presumed to be incompetent, except under certain specified conditions that may vary from state to state.
- competing stimuli** Stimuli that displace the problem behavior, such as providing food or mouthing toys to children who display pica (eating of nonfood items).
- competitive employment** To engage in competitive employment, individuals with disabilities must have the same skills requisite for any employee to succeed in the workplace: knowledge base for the job, appropriate social skills, effective communication skills, and motivation. Individuals with disabilities also must have appropriate independent living skills and the skills and abilities to manage their disability-related needs, such as hiring and managing personal care attendants and transportation services.
- complementary health approaches (CHA)** The use of nonmainstream approaches together with conventional medical approaches; *previously called* complementary and alternative medicine (CAM).
- complete learning trials** Refers to an opportunity to respond that is controlled by the trainer.
- compliance training** An important prerequisite to instructional training. The instructor orients the child to attend to the instructor and then issues a developmentally appropriate “do” request.
- compounding pharmacy** A special pharmacy that can make drug formulations that are specifically tailored to patients such as liquid suspensions, suppositories, and creams.
- compulsions** Repetitive behaviors (e.g., hand washing) or mental acts (e.g., praying and counting) that are done to neutralize an obsession or as part of following rigid rules.
- computed tomography (CT)** An imaging technique in which x-ray “slices” of a structure are viewed and synthesized by a computer, forming an image. CT scans are less clear than magnetic resonance imaging (MRI) scans but are better at localizing certain tumors and areas of calcification.
- concave** Having a curved, indented surface.
- concussion** A clinical syndrome caused by a blow to the head, characterized by transient loss of consciousness.
- conductive** In reference to hearing the conduction and amplification of sound through the middle ear.
- conductive hearing loss** Hearing loss resulting from a problem in conducting sound waves anywhere along the route through the outer ear, eardrum, or middle ear.
- cones** Photoreceptor cells of the eye associated with color vision.
- congenital** Originating prior to birth.
- congenital cytomegalovirus (CMV)** One of the most common congenital infections that can result in premature birth, growth restriction, microcephaly, seizures, and hearing loss.
- congenital myopathies** A group of inherited muscle disorders often associated with mitochondrial dysfunction.
- congenital varicella syndrome (VZV)** A rare congenital infection resulting from maternal chickenpox during the first two trimesters of pregnancy. The characteristic symptoms in the newborn consist of skin lesions, neurologic defects, and eye and skeletal anomalies.
- congenital zika syndrome (CZS)** A recently described congenital viral infection resulting in severe microcephaly in affected infants.
- conjunctiva** The mucous membrane that lines the inner surface of the eyelid and the exposed surface of the eyeball.
- consanguinity** Familial relationship, such as the marriage of first cousins.
- conscience** A personal sense, generally intuitive and urgent, of the way one should respond under specific circumstances.
- consequences** Events or contextual factors that occur subsequent to a behavior and may or may not be causally related to it.
- conservatorship** A circumstance in which the court declares an individual unable to take care of legal matters and appoints another individual (a conservator) to handle these matters on the individual’s behalf.
- contiguous gene syndrome** A genetic syndrome resulting from defects in a number of adjacent genes.
- contingent stimulation** Applying punishment following the occurrence of a misbehavior.
- contingent withdrawal** The removal of access to positive reinforcement following a misbehavior.
- continuous positive airway pressure (CPAP)** Involves providing a mixture of oxygen and air under continuous pressure; this prevents the alveoli from collapsing between breaths.
- continuum** A spectrum.
- contracture** A shortening of muscle fibers and soft tissue around a joint that causes decreased mobility and is almost always irreversible.
- contralateral** Opposite side.
- contusion (of brain)** Structural damage limited to the surface layer of the brain caused by trauma.

- convex** Having a curved, elevated/protruding surface, such as a dome.
- cooperative learning** An instructional method that includes a range of team-based learning strategies.
- cooperative play** The developmental stage when young children start to play collaboratively with their peers to achieve a common goal, usually around 4–6 years.
- copy number variability (CNV)** When the number of copies of a particular gene varies from one individual to the next.
- cordocentesis** *See* percutaneous umbilical blood sampling (PUBS).
- cornea** The clear dome that covers and protects the iris of the eye.
- corpus callosotomy** Surgical procedure in which the corpus callosum is cut to prevent the generalized spread of seizures from one hemisphere to another.
- corpus callosum** The bridge of white matter connecting the two cerebral hemispheres and permitting the exchange of information between the two hemispheres.
- corpus striatum** Part of the basal ganglia of the brain, comprising the caudate and lentiform nuclei.
- cortex** The surface of the cerebral hemisphere, composed principally of neurons and glia.
- cortical** Pertaining to the cortex or gray matter of the brain.
- cortical visual impairment** Visual impairment caused by damage to the part of the brain related to vision. Although the eye is normal, the brain cannot properly process the information it receives. The degree of vision loss may be mild or severe and can vary greatly, even from day to day.
- corticospinal pathways** White matter pathways leading from the brain through the spinal corticospinal tract; *see* pyramidal tract.
- cortisol** A steroid.
- CPR** *See* cardiopulmonary resuscitation.
- CPT** *See* chest physiotherapy.
- cranial sutures** Fibrous material connecting skull bones.
- craniofacial** Relating to the skull and bones of the face.
- craniosynostosis** Premature closure of cranial bones.
- creatinine** Product produced by muscle tissue and normally filtered from the blood by the kidney.
- creatine kinase (CK)** An enzyme released by damaged muscle cells. Its level is elevated in muscular dystrophy.
- crib death** *See* sudden infant death syndrome (SIDS).
- Crohn's disease** An inflammatory bowel disorder.
- crossover** The exchange of genetic material between two closely aligned chromosomes during the first meiotic division.
- cryotherapy** The use of freezing temperatures to destroy tissue.
- cryptorchidism** Undescended testicles.
- crystallized intelligence** The part of intellectual functioning that involves the use of knowledge and experience to problem solve.
- C-section** *See* cesarean section.
- CSF** *See* cerebrospinal fluid.
- CT** *See* computed tomography.
- cultural competence** Knowledge of the norms of other cultures and how to partner with patients of various backgrounds.
- customized employment** A blend of services designed to increase employment options for individuals with significant disabilities such as self-employment, entrepreneurship, job carving and restructuring, personal agents, and customized training.
- CVA** *See* cerebral vascular accident.
- CVS** *See* chorionic villus sampling.
- cyanosis** A bluish discoloration of the skin resulting from poor circulation or inadequate oxygenation of the blood.
- cystic fibrosis** An autosomal recessively inherited disorder of the secretory glands leading to malabsorption and lung disease.
- cystometrogram (urodynamics)** A procedure in which fluid is injected into the bladder and pressure is measured.
- cytokines** A group of molecules that are either pro- or anti-inflammatory and are part of the human immune system.
- cytomegalovirus (CMV)** A virus that may be asymptomatic or cause symptoms in adults that may resemble mononucleosis. In the fetus, it can lead to severe abnormalities including microcephaly, seizures, hearing loss, retinitis, and delayed development.
- cytoplasm** The contents of the cell outside the nucleus.
- cytosine** One of the four nucleotides (chemicals) that comprise DNA.
- cytotoxicity** Being toxic to cells.
- DAI** *See* diffuse axonal injury.
- dB** *See* decibel.
- DDH** *See* developmental dislocation of the hip.
- debridement** The removal of dead tissue (e.g., after a burn or an infection).
- decibel (dB)** A measure of loudness, used in hearing testing.
- decubitus ulcers** Bed sores.
- delay** In developmental disabilities, refers to simply to a slower than expected rate in the acquisition of skills, usually defined with reference to widely accepted developmental milestones.
- deletion** Loss of genetic material from a chromosome.
- delirium** An organically based psychosis characterized by impaired attention, disorganized thinking, altered and fluctuating levels of consciousness, and memory impairment. It may be caused by encephalitis, diabetes, or intoxication and is usually reversed by treating the underlying medical problem.
- delusions** False beliefs, often quite bizarre, that are symptoms of psychosis or drug intoxication.
- dementia** A progressive neurological disorder marked by the loss of memory, decreased speech, impairment in abstract thinking and judgment, other disturbances of higher cortical function, and personality change (e.g., Alzheimer's disease).

- dendrite** A short branched extension of a nerve cell, along which impulses received from other cells at synapses are transmitted to the cell body.
- dental caries** Tooth decay.
- dental lamina** A thickened band of tissue along the future dental arches in the human embryo.
- dental organ** The embryonic tissue that is the precursor of the tooth; *also called* tooth bud.
- dental plaque** Patches of bacteria, bacterial byproducts, and food particles on teeth that predispose them to decay.
- dental sealant** Plastic substance administered to teeth, most commonly the molars, to increase their resistance to decay.
- dentin** The principal substance of the tooth surrounding the tooth pulp and covered by the enamel.
- deoxyribonucleic acid (DNA)** The fundamental component of living tissue. It contains an organism's genetic code.
- depolarization** The eliminating of the electrical charge of a cell.
- depolarizing current** An electrical current causing a change in cell membrane voltage.
- depressed fracture** Fracture of bone, usually the skull, that results in an inward displacement of the bone at the point of impact. It requires surgical intervention to prevent damage to underlying tissue.
- deprivation** In behavior management, denial of access to a reinforcing item or event.
- dermal sinus** A cavity lining extending from the skin surface to a deeper structure, most notably the spinal cord.
- descriptive analysis** Involves the quantitative, direct observation of the individual's behaviors as well as antecedent events and consequences under naturalistic conditions.
- descriptive and functional analysis** Observation period in behavior management that precedes treatment.
- detoxification** The conversion of a toxic compound to a nontoxic product.
- developmental cerebellar cognitive affective syndrome** A syndrome described in children who survive prematurity-related cerebellar injury and have deficits that range from impaired executive function to severe behavioral disturbances that fall on the autism spectrum.
- developmental coordination disorder (DCD)** A non-progressive disorder of childhood unassociated with a specific neurologic disorder (e.g., cerebral palsy). It is associated with impairments in skilled motor movements that are appropriate for the child's chronological age and thereby interferes with activities of daily living.
- developmental delays** Refers to a significant lag in the attainment of milestones in one or more areas of development.
- developmental deviance** Refers to nonsequential unevenness in the achievement of milestones within one or more streams of development.
- developmental disabilities** A group of chronic conditions that are attributable to an impairment in physical, cognitive, speech/language, psychological, or self-care areas and that are manifested during the developmental period (younger than 21 years of age).
- developmental dislocation of the hip (DDH)** A congenital hip dislocation, usually evident at birth, occurring more commonly in girls.
- developmental dissociation** Refers to a significant difference in developmental rates between two areas.
- developmental dysarthria** Difficulty with speech due to congenital impairment of oral motor structures or musculature.
- developmental milestone** A physical, language, or adaptive ability that is achieved by most infants and young children by a certain age.
- developmental regression** Loss of previously attained milestones.
- developmental surveillance** The evaluation of a child's developmental performance during the routine provision of health care.
- deviate** *See* diverge.
- dextrose** A simple sugar similar to glucose and used to medically correct or prevent low blood sugar.
- diagnostic overshadowing** A situation where health professionals wrongly presume that present symptoms are a consequence of their patient's underlying condition rather than being a new condition.
- diagnostic test** A test used to definitively confirm or exclude the presence of a disease or condition in a particular individual.
- dialysis** A detoxification procedure of the blood (i.e., hemodialysis) or across the peritoneum (i.e., peritoneal dialysis) used to treat kidney failure.
- diaphysis** The shaft of a long bone lying under the epiphysis.
- diastematomyelia** A congenital defect in which the spinal cord is divided into halves by a bony or cartilaginous divider, often seen in spina bifida.
- diencephalon** A part of the forebrain.
- differential reinforcement** A behavior management technique in which a preferred alternate behavior is positively reinforced while a less preferred behavior is ignored.
- differential reinforcement of alternative behaviors (DRA)** When the delivery of the reinforcer is contingent on the performance of alternative, more appropriate behaviors.
- differential reinforcement of other behaviors (DRO)** Consists of the delivery of reinforcers (e.g., attention) contingent on the absence of problem behaviors.
- diffuse** Spread out.
- diffuse axonal injury (DAI)** Diffuse injury to nerve cell components, usually resulting from shearing forces. This type of traumatic brain injury is commonly associated with motor vehicle accidents.
- diffusion-weighted imaging (DWI)** A form of magnetic resonance imaging (MRI) scanning that can identify

- with great sensitivity areas of brain, especially white matter, that have suffered an acute injury.
- dipters** Units of refractive power of a lens (e.g., glasses).
- diplegia** A form of spastic cerebral palsy, most often found in former premature babies, in which the legs are predominantly affected.
- diploid** Having paired chromosomes in nondividing cells (i.e., 46 chromosomes in 23 pairs).
- diplopia** Double vision.
- direct instruction (DI)** A codified approach to teacher-led instruction that provides explicit instruction with teacher modeling, extensive practice through choral response, brisk pacing, and immediate corrective feedback. The DI technique is very successful for teaching fundamental reading skills and building reading fluency and reading comprehension.
- disability** Refers to decreased in the ability to perform some action, engage in some activity, or participate in some real-life situation or setting.
- discrepancy model** In education this is often called the “wait-to-fail” model. As the child ages, they will fall far enough behind to have a significant difference between their ability (IQ) and their achievement.
- dislocation** The displacement of a bone out of a joint space.
- disorders of carbohydrate metabolism** Inborn errors of metabolism involving enzyme deficiencies in the breakdown of sugars.
- dissociated** Not associated with.
- dissociation** A child may demonstrate an uneven pattern of skills, such that in some areas progress is fairly typical whereas in other areas the child demonstrates a significant departure (delay or deviation) from the expected course.
- distal** Involving muscles or body segments farther from the center of the body.
- distension** Abdominal distension is due to an accumulation of air, fluid, or food.
- diuretics** Medications used to reduce intercellular fluid buildup in the body (edema), especially in the lungs.
- diving reflex** Named for its presence in diving seals, this also occurs in infants during hypoxic ischemic encephalopathy (HIE) and results in the redistribution of blood away from “nonvital organs” (e.g., kidneys, liver, lungs, intestines, and skeletal muscles) to preserve the perfusion of the “vital organs” (i.e., heart, brain, and adrenal glands). This reflex, if prolonged, may result in insufficient blood supply and damage to the nonvital organs.
- DMD** See Duchenne muscular dystrophy.
- DNA** See deoxyribonucleic acid.
- DNR** See do not resuscitate.
- do not resuscitate (DNR)** Medical orders that state that, should a patient develop a cardiopulmonary arrest, no attempts at resuscitation would be undertaken; also called “No Code” orders.
- dominant** In genetics, referring to a trait that only requires one copy of a gene to be expressed phenotypically. For example, having brown eyes is a dominant trait, so a child receiving a gene for brown eyes from his or her mother or father (or from both parents) will have brown eyes.
- dopamine** A neurotransmitter involved in attention deficits (e.g., attention-deficit/hyperactivity disorder [ADHD]) and motor function (e.g., Parkinson’s disease).
- dorsal** Back.
- dorsal induction** Describes the processes of primary and secondary neurulation during embryogenesis.
- dorsiflexion** Upward movement of the foot.
- dorsolateral** Involving both the back and side of a body part.
- double effect** Principle of a moral argument used to defend certain actions that can be anticipated to have both good and bad outcomes.
- double helix** The coiled structure of DNA; a structure that resembles a twisted ladder.
- drug–disease interaction** An event in which a *drug* that is intended for therapeutic use causes harmful effects in a patient because of a *disease* or condition that the patient has.
- drug–drug interaction** An event in which a *drug* that is intended for therapeutic use causes a side effect in a patient because of an interaction with another *drug* the patient is receiving.
- dual diagnosis** Refers to a combination of an intellectual disability and psychiatric disorder.
- dual discrepancy model** The student *both* performs below the level evidenced by classroom peers and shows a learning rate substantially below that of classroom peers.
- Duchenne muscular dystrophy (DMD)** See Appendix B.
- ductus arteriosus** An arterial connection open during fetal life that diverts the blood flow from the pulmonary artery into the aorta, thereby bypassing the not-yet-functional lungs.
- ductus venosus** Open during fetal life, it is a shunt that allows oxygenated blood from the placenta to bypass the liver and return to the systemic circulation for distribution to the rest of the body.
- duodenal** Pertaining to the first section of the small intestine.
- duodenal atresia** Congenital absence of a portion of the first section of the small intestine; often seen in individuals with Down syndrome.
- duodenum** The first part of the small intestine; the upper part of the small intestine.
- DWI** See diffusion-weighted imaging.
- dynamic** In the context of orthotics, capable of active movement.
- dysarthria** Difficulty with speech due to impairment of oral motor structures or musculature.
- dyscalculia** Learning disability affecting skills in mathematics.
- dyscontrol syndrome** Intermittent explosive disorder out of proportion to the event that provokes it.
- dysesthesias** Abnormal sensation, especially to touch, such as burning or electric shock.

- dysgraphia** Learning disability in areas of processing and reporting information in written form.
- dyskinesia** An impairment in the ability to control movements characterized by spasmodic or repetitive motions.
- dyskinetic cerebral palsy** Type of “extrapyramidal” cerebral palsy often involving abnormality of the basal ganglia and manifesting as rigidity, dystonia, or choreoathetosis.
- dyslexia** Learning disability affecting reading skills; *also called* specific reading disability.
- dysmorphic** Unusual physical appearance as a result of a genetic disorder.
- dysmorphology** The study of birth defects, particularly those affecting the anatomy of the child.
- dysmotility** Abnormal motility of the gut.
- dysostosis** An abnormal bony formation.
- dysphagia** Difficulty in swallowing.
- dysphasia** Impairment of speech consisting of a lack of coordination and failure to arrange words in proper order due to a central brain lesion.
- dysplasia** Abnormal tissue development.
- dyspraxia** Inability to perform coordinated movements despite normal function of the central and peripheral nervous systems and muscles.
- dysthymia** A mild form of depression characterized by a mood disturbance that is present most of the time and is associated with feelings of low self-esteem, hopelessness, poor concentration, low energy, and changes in sleep and appetite; seen most commonly in adolescents.
- dystocia** Structural abnormalities of the maternal pelvis that cause a difficult labor or childbirth.
- dystonia** A disorder of the basal ganglia associated with altered muscle tone leading to contorted body positioning; a movement disorder.
- dystonic** Contorted body positioning resulting from disorder of the basal ganglia.
- dystonic cerebral palsy** A form of dyskinetic cerebral palsy, the most prominent feature of which is dystonia.
- E. coli** *See Escherichia coli.*
- Eagle-Barrett syndrome** Formerly “prune belly syndrome.”
- early intervention (EI)** *See* Chapter 31.
- ECG** *See* electrocardiogram.
- echocardiography** An ultrasonic method of imaging the heart. It can be used to detect congenital heart defects even prior to birth.
- echolalic** Pertaining to immediate or delayed repetition of a word or phrase said by others; often evident in children with autism spectrum disorder.
- echolalia** *See* echolalic.
- ECMO** *See* extracorporeal membrane oxygenation.
- ectoderm** Outer cell layer in the embryo.
- ectodermal dysplasia** A diverse group of genetic disorders that involve defects of the hair, nails, teeth, skin, and glands. *See* Appendix B.
- ectopia** Abnormal congenital or acquired position of a body organ.
- ectopic** Pertaining to ectopia.
- ectopic pregnancy** Embryo implanted outside of the uterus.
- ectrodactyly** Congenital absence of all or parts of digits.
- eczema** A common skin condition, often occurring in childhood, marked by an itchy inflammatory reaction manifested by tiny blisters with reddening, swelling, bumps, and crusting; *also called* atopic dermatitis.
- EDC** *See* estimated date of confinement.
- EDD** Estimated due date; *also called* estimated date of confinement.
- edema** An abnormal accumulation of fluid in the tissues of the body.
- EEG** *See* electroencephalogram.
- efferent** Pertaining to the impulses that go to a nerve or muscle from the central nervous system (CNS); for example, motor fibers transmit impulses from the brain to initiate movement.
- effusion** A middle-ear infection associated with fluid accumulation.
- EI** *See* early intervention.
- Ehlers-Danlos syndrome** *See* Appendix B.
- EKG** *See* electrocardiogram.
- ELBW** *See* extremely low birth weight.
- electrocardiogram (EKG, ECG)** The graphic record of an electronic recording of heart rate and rhythm.
- electroencephalogram (EEG)** A recording of the electrical activity in the brain that is often used in the evaluation of seizures.
- electrolytes** Minerals contained in the blood, such as sodium, potassium, and chloride.
- electromyography (EMG)** A technique for measuring muscle activity and function; recording of electric currents associated with muscle contractions are useful in the diagnosis of a variety of neuromuscular disorders, including anterior horn cell disease, neuropathies, neuromuscular junction disorders, and some myopathies.
- electroretinogram (ERG)** A graphic record of the electrical activity of the retina.
- eloquent cortex** The area of the cortex involved in the production of speech.
- emancipated minor** A teenage minor who is legally free of parental control for giving informed consent to any medical treatment.
- embryo** The earliest stage of conceptional development after fertilization and during the first 8 weeks of pregnancy. The placenta and most of the primitive organs are formed into the major systems during this time.
- embryoblasts** The mass of cells inside the early embryo that will eventually give rise to the structures of the fetus.
- embryotic period** The first 8 weeks of pregnancy.
- EMG** *See* electromyography.
- enamel** The calcified outer layer of the tooth.
- encephalitis** Inflammation of the brain, generally from a viral infection.
- encephalocele** A neural tube defect characterized by a sac-like protrusion of the brain and the membranes that cover it through an opening in the skull. This defect is

- caused by failure of the neural tube to close completely during fetal development.
- encephalopathy** Disorder or disease of the brain.
- enclaves** Once considered a viable employment option for individuals with severe disabilities; it brings together groups of individuals with disabilities at one site with a common job coach engaged around a work task.
- endocardial cushion defect** A congenital heart defect, found often in Down syndrome, where there is a lack of closure of the wall separating the two sides of the heart.
- endocarditis** Inflammation of the inner lining of the heart.
- endochondral ossification** Formation of bone from cartilage.
- endocrine disruptors** Chemicals that may interfere with the body's hormonal system and produce adverse developmental, reproductive, neurological, and immune effects.
- endoderm** The inner cell layer in the embryo.
- enriched environments** A type of treatment that focuses on providing stimuli that compete with problem behaviors.
- enteral nutrition** Feeding directly into the stomach through the nose or mouth to ensure that nutritional requirements are met.
- enteric nervous system** The subdivision of the autonomic nervous system that controls the gastrointestinal system.
- enterobacter** A rod-shaped bacteria that can cause gastrointestinal symptoms.
- enuresis** Involuntary urination especially at night in children.
- ependymomas** Tumors developing from cells that line both the hollow cavities-ventricles of the brain and the canal containing the spinal cord.
- epicanthal folds** Crescent-shaped fold of skin on either side of the nose, commonly associated with Down syndrome.
- epidemiology** The study of the distribution and determinants of disease frequency in specific populations.
- epidural anesthesia** Pain relief by infusing an anesthetic agent into the epidural space of the spine.
- epidural hematoma** Localized collection of clotted blood lying between the skull and the outer (dural) membrane of the brain, resulting from the hemorrhage of a blood vessel resting in the dura. This most often results from traumatic head injury.
- epigastric** Relating to the region around the upper abdomen near the stomach.
- epigenetics** Changes in gene expression that do not permanently alter the DNA sequence.
- epiglottis** A lid-like structure that hangs over the entrance to the windpipe and prevents aspiration of food or liquid into the lungs during swallowing.
- epilepsy** A disorder of the brain characterized by repeated seizures and by the neurobiologic, cognitive, psychological, and social consequences of this condition. *See* Chapter 22.
- epiphyses** The end plates of long bones where linear growth occurs.
- epithelial** Pertaining to cells that are found on exposed surfaces of the body (e.g., skin, mucous membranes, and intestinal walls).
- equinus** Involuntary extension (plantar flexion) of the foot (like a horse); this position is often found in spastic cerebral palsy. It leads to toe walking.
- ERG** *See* electroretinogram.
- erythrocytosis** An abnormal increase in the number of circulating red blood cells.
- erythropoietin** A protein that regulates red blood cell production.
- Escherichia coli (E. coli)** Bacteria that can cause infections ranging from diarrhea to urinary tract infection to sepsis.
- esophageal atresia** A congenital defect in which there is a stricture in the esophagus, preventing food from entering the stomach.
- esophagus** Tube through which food passes from the pharynx to the stomach.
- esotropia** A form of strabismus in which one or both eyes turn in; "cross-eyed."
- estimated date of confinement (EDC)** Expected date of delivery; *also called* estimated due date (EDD).
- estrogen** Female sex hormone.
- etiology** Refers to the cause of a medical condition.
- eustachian tube** Connection between oral cavity and middle ear, allowing equilibration of pressure and drainage of fluid.
- everted** Turned outward.
- evidence-based research instruction** Defined as "research that involves the application of rigorous, systematic, and objective procedures to obtain reliable and valid knowledge relevant to education activities and programs" (U.S. Department of Education, 2007).
- excitotoxic** Pertaining to excitotoxins—neurochemicals that can cause neuronal cell death and have been implicated in hypoxic brain damage and acquired immunodeficiency syndrome encephalopathy.
- executive function** The cognitive tasks related to taking in, organizing, processing, and acting on information. Deficits are present in people with autism spectrum disorder (ASD), learning differences, and attention-deficit/hyperactivity disorder.
- exfoliation** Refers to the removal of the oldest dead skin cells or the shedding of teeth.
- exome** The portions of a gene (or the entire genome) that code information for protein synthesis.
- exons** *See* exome.
- exon skipping** A novel therapy involving a medication that enables RNA splicing to cause cells to "skip" over faulty sections of genetic code, leading to a truncated but still functional protein despite the genetic mutation.
- exotropia** A form of strabismus in which one or both eyes turn out; "wall-eyed."
- expressive language** Communication by spoken language, gesture, signing, or body language.

- extended release** A form of medication that gradually releases its compound leading to a prolonged period of activity, often 8–12 hours.
- extension** Movement of a limb at a joint to bring the joint into a more straightened position.
- extinction** The process through which reinforcement is withheld for a previously reinforced response, resulting in a decrease in the future occurrence of that response; *see* planned ignoring.
- extinction burst** A transient increase in the frequency and intensity of a challenging behavior before a subsequent reduction occurs.
- extracorporeal membrane oxygenation (ECMO)** An extreme and invasive life support technique that involves putting a patient onto a heart–lung bypass machine.
- extract** In the context of medication, a concentrated preparation.
- extrapyramidal cerebral palsy** *See* dyskinetic cerebral palsy.
- extrapyramidal system** Areas of the brain involved in subconscious, automatic aspects of motor coordination.
- extremely low birth weight (ELBW)** Term often used to describe an infant with a birth weight less than 1,000 grams (2 1/4 pounds).
- fading** Behavioral instruction process by which prompts are withdrawn gradually.
- FAE** Fetal alcohol effects. *See also* Fetal alcohol spectrum disorder (FASD).
- failure to thrive (FTT)** Inadequate growth of both weight and height in infancy or early childhood caused by malnutrition, chronic disease, or a congenital anomaly.
- false-negative result** A test result that indicates that a person does not have a specific disorder when the person actually does have the condition.
- false-positive result** A test result that indicates that a person has a specific disorder when the person actually does not have the condition.
- family-centered care** An approach to health care that is based on mutual respect that promotes optimal health outcomes and treatment adherence by encouraging shared decision making in daily patient interactions.
- family therapy** A type of psychotherapy that involves all members of a nuclear family.
- fatty acid oxidation disorders** Inborn errors of metabolism involving enzyme deficiencies in the breakdown of fatty acids. *See* Appendix B.
- febrile** Having an elevated body temperature. A child is considered febrile when registering a fever above 100.4°F (38°C).
- FEES** Flexible endoscopic evaluation of swallowing.
- Feingold diet** This diet involves removing synthetic colors, flavors, artificial preservatives, salicylates, and sweeteners from the diet.
- femur** Long bone in the thigh connecting the hip to the knee.
- fencer's response** *See* asymmetrical tonic neck reflex (ATNR).
- fertilization** The entrance of a sperm into the egg, resulting in a conception.
- FES** *See* functional electrical stimulators.
- fetal alcohol effects (FAE)** Former term for alcohol-related neurodevelopmental disorder (ARND; *see* Chapter 2).
- fetal alcohol spectrum disorders (FASD)** Umbrella term for a range of physical and neurodevelopmental disabilities associated with prenatal alcohol exposure.
- fetal heart rate (FHR)** Normally 120–140 beats per minute and routinely monitored by ultrasound throughout labor to indicate fetal well-being versus fetal distress (i.e., FHR < 100).
- fetal heart rate monitoring** Monitoring fetal heart rate with ultrasound.
- fetal period** The time of pregnancy between the 10th week and birth.
- FHR** *See* fetal heart rate.
- fibroma** A benign fibrous tumor of connective tissue.
- FISH** *See* fluorescent *in situ* hybridization.
- fissures** On the brain, these are deeper than sulci, are first visible during fetal development, and separate each hemisphere into four functional areas or lobes.
- flexion** Movement of a limb to bend at a joint.
- flexor** A muscle with the primary function of flexion or bending at a joint.
- flexor and extensor spasms** Spasms of bending of a limb toward or away from the body.
- flora** In medicine, bacteria normally residing within a body organ and not causing disease, such as *E. coli* in the intestine.
- fluency** Aspect of speech, that is, producing speech in a fluid manner.
- fluid intelligence** The general ability to think abstractly, reason, identify patterns, solve problems, and discern relationships.
- fluorescent in situ hybridization (FISH)** Technology used to diagnose a number of microdeletion syndromes.
- fluorosis** A chronic condition caused by excessive intake of fluoride containing compounds, marked by mottling of the teeth.
- fMRI** *See* functional magnetic resonance imaging.
- focal** Localized.
- focal neurological changes** Findings on neurological exams that are abnormal and indicative of a lesion in a particular location in the brain; *also called* focal neurological impairments.
- folic acid** A vitamin, a deficiency of which during early pregnancy has been linked to neural tube defects.
- foramen ovale** A tiny window between the right atrium and the left atrium.
- forebrain** The front portion of the brain during fetal development; *also called* the prosencephalon.
- forward chaining** A behavior management technique in which the first skill in a sequence is taught first and the last skill is taught last.
- fovea** *See* fovea centralis.

- fovea centralis** The small pit in the center of the macula; the area of clearest vision, containing only cones.
- frame shift** A type of gene mutation in which the insertion or deletion of a single nucleotide leads to the misreading of all subsequent codons as the three base pair reading frame is shifted.
- free level** In pharmacotherapy, the amount of active drug that is able to produce an effect on the body.
- free radicals** Chemical compounds, the abnormal accumulation of which has been linked to cancer and neurotoxicity.
- frequency** Cycles per second, or hertz (Hz), a measure of sound.
- frontal lobe** Controls both voluntary motor activity and important aspects of cognition.
- FTT** *See* failure to thrive.
- full mutation** Having over 200 CGG repeats causing the clinical expression in a triplet repeat disorder such as fragile X syndrome.
- functional (experimental) analysis** *See* applied behavioral analysis.
- functional electrical stimulators (FES)** Provide neural stimulation to increase mobility.
- functional magnetic resonance imaging (fMRI)** A neuroimaging procedure that permits evaluation of the effects of activities, such as reading, on brain function.
- fundoplication** An operation in which the top of the stomach is wrapped around the opening of the esophagus to correct gastroesophageal reflux disease (GERD).
- FXS** Fragile X syndrome (*see* Chapter 15).
- G tube** *See* gastrostomy tube.
- GABA** *See* gamma-aminobutyric acid.
- galactosemia** An inborn error of metabolism involving an enzyme deficiency that prevents the breakdown of the sugar galactose, a component of many foods. *See* Appendix B.
- gamma-aminobutyric acid (GABA)** An amino acid that acts as an inhibitory neurotransmitter.
- ganglia** Masses of nerve cell bodies.
- gastric tube** A tube inserted through the abdominal wall that delivers nutrition directly to the stomach.
- gastrocolic reflex** A trigger that results in an urge to defecate; it generally occurs 30–60 minutes after a meal.
- gastroenteritis** An acute illness marked by vomiting and diarrhea usually associated with a viral infection (e.g., rotavirus in infants) that generally lasts a few days; *also called* stomach flu.
- gastroesophageal duodenoscopy** Endoscopy in which a flexible instrument with a light source examines the esophagus, stomach, and small bowel.
- gastroesophageal reflux disease (GER/GERD)** The backward flow of food into the esophagus after it has entered the stomach; acid reflux.
- gastrointestinal (GI) tract** The stomach and small intestine.
- gastrojejunal (G-J) tube** A feeding tube that is inserted through a gastrostomy site and threaded through the stomach and duodenum into the jejunum (the second part of the small intestine).
- gastrojejunostomy (G-J)** Surgical procedure to prepare for gastrojejunostomy (G-J) tube.
- gastroschisis** Congenital malformation of the abdominal wall resulting in the protrusion of abdominal organs.
- gastrostomy** An operation in which an artificial opening is made into the stomach through the wall of the abdomen. This is usually done in order to place a feeding tube into the stomach.
- gastrostomy (G) tube** A permanent tube placed directly through the skin and into the stomach.
- gastrulation stage** The phase early in embryonic development during which the single-layered blastula is reorganized into a three-layered structure (the ectoderm, mesoderm, and endoderm).
- GBS** *See* group B *Streptococcus*.
- GDD** *See* global developmental delay.
- gene** A molecular unit of heredity consisting of stretches of DNA and RNA that code for a type of protein or for an RNA chain that has a function in the organism.
- gene editing** The use of biotechnological approaches to make changes to specific DNA sequences in the genome.
- gene therapy** The transplantation of normal genes into cells in place of missing or defective ones in order to correct genetic disorders.
- genome** The complete set of hereditary units (genes) in an organism.
- genomic imprinting** A condition manifested differently depending on whether the trait is inherited from the mother or father; *also called* uniparental disomy. An example is a deletion in chromosome 15q11–q13, which, when inherited from the mother, results in Angelman syndrome and, when inherited from the father, results in Prader-Willi syndrome. *See* Chapter 1 and Appendix B.
- genotype** The genetic composition of an individual.
- genu varum** Bowed legs.
- GERD** *See* gastroesophageal reflux.
- germ cells** The cells involved in reproduction (i.e., sperm, eggs).
- German measles** *See* rubella.
- germinal stage** Begins with conception and ends when the blastocyst is fully implanted into the uterine wall.
- gestational age (GA)** The measure of the duration of a pregnancy in weeks, usually taken from the date of the woman's last menstrual period.
- GI** *See* gastrointestinal tract.
- gingiva** The gums.
- gingivitis** Gum inflammation.
- G-J tube** *See* gastrojejunal tube.
- glaucoma** Increased pressure within the anterior chamber of the eye that can cause blindness.
- glia** Cells that compose the white matter and provide a support function for neurons.
- glial** Pertaining to glia.
- global developmental delay (GDD)** Significant delays in development of two or more of the following domains:

- gross motor/fine motor, speech/language, cognition, social/personal, and activities of daily living (ADL).
- globus pallidus** A subcortical area of the brain that is a major component of the basal ganglia and is part of the extrapyramidal system.
- glossoptosis** Downward or backward displacement of the tongue, as in Down syndrome.
- glucose** A simple sugar that is an important energy source and is a component of many carbohydrates.
- glutaminergic neurons** Brain cells that release the chemical glutamate, an excitatory neurotransmitter.
- gluten-/casein-free diet** Involves removing all wheat and milk products from the child's diet.
- glycine** An amino acid that is a constituent of most proteins and can serve as an excitatory neurotransmitter.
- glycogen** The chief carbohydrate stored in the body, primarily in the liver and muscles.
- GMFCS** See gross motor function classification system.
- goiter** Enlargement of the thyroid gland.
- Golgi apparatus** The intracellular organelle that packages proteins in a form that can be released through the cell membrane and carried throughout the body.
- goniometry** Use of a hinged measuring tool to determine joint range of motion.
- graduated guidance** A behavior management technique in which only the level of assistance (guidance) necessary for the child to complete the task is provided.
- graft-versus-host disease** A mechanism of the body's immune system that destroys foreign proteins. It can be life-threatening when it occurs in a child who has received a bone marrow or organ transplant and has a suppressed immune system. Symptoms include diarrhea, skin breakdown, and shock.
- grammar** The system of and rules for using units of meaning (morphemes) and syntax in language.
- grapheme** A unit, such as a letter, of a writing system.
- gravida/para** The number of times a woman has been pregnant (gravid) and has delivered (parous) a living infant.
- grey matter** The part of the brain rich in neurons. It comprises the cortex.
- gross motor function classification system (GMFCS)** An assessment of ambulatory ability for children with cerebral palsy.
- group B *Streptococcus* (GBS)** Bacteria, causing one of the most common and severe neonatal infections.
- guanine** One of the four nucleotides (chemicals) that comprises DNA.
- guided compliance** A behavior management technique involving the use of graduated guidance to teach functional tasks.
- Guillain-Barré syndrome** An acute inflammatory peripheral neuropathy (see Appendix B).
- gynecomastia** Excessive breast growth in males.
- gyri** Convolutions of the surface of the brain; *singular*: gyrus.
- habilitation** The teaching of new skills to children with developmental disabilities. It is called habilitation rather than rehabilitation because these children did not possess these skills previously.
- Haemophilus influenzae** A bacteria that can cause serious infections in children including meningitis.
- hallucinations** Sensory perceptions without a source in the external world. These most commonly occur as symptoms of psychosis, drug intoxication, or seizures.
- hamartomas** A benign (not cancer) growth made up of an abnormal mixture of cells and tissues normally found in the area of the body where the growth occurs.
- hand splints** A form of low-tech assistive device for children with cerebral palsy or neuromuscular disorder.
- haploid** Having a single set of human chromosomes (23), as in the sperm or egg.
- hCG** See human chorionic gonadotropin.
- health disparities** Racial or ethnic differences in the quality of health care that are not due to access-related factors or clinical needs, preferences, and appropriateness of intervention.
- health equity** The absence of systematic disparities in health or social determinants of health between social groups who have different levels of underlying social advantage or disadvantage.
- health literacy** The capacity to obtain, process, and understand basic health information and services that are needed to make appropriate decisions about one's own or one's child's health.
- hearing loss** A condition characterized by a decrease in the ability to hear based on decreased intensity, loudness as measured in decibels (dB), or frequency of sound.
- hemangiomas** Congenital abnormal masses of blood vessels, such as "birth marks."
- hematocrit** Percentage of red blood cells in whole blood, normally about 35%–40%.
- hematologic** Relating to the blood system.
- hematopoietic** Relating to the formation of red blood cells.
- hematuria** Blood in the urine.
- hemihypertrophy** Asymmetric overgrowth of the face or limbs.
- hemiplegia** Spasticity and weakness on one side of the body.
- hemispherectomy** Surgical removal of most of one cerebral hemisphere for treatment of intractable generalized seizures.
- hemodialysis** A detoxification procedure in which an individual's blood is gradually removed through an artery, passed through an artificial kidney machine, and then returned cleansed. It is used most commonly to treat end stage renal disease.
- hemoglobin** Blood protein capable of carrying oxygen to body tissues.
- hemolytic** Excessive breakdown of red blood cells.
- hemolytic anemia** Anemia due to the destruction of red blood cells.
- hemostat** A small surgical clamp used to constrict a tube or blood vessel.

- hepatomegaly** Enlarged liver.
- hepatosplenomegaly** Enlargement of the liver and spleen.
- herpes simplex virus (HSV)** A virus that can lead to symptoms that range from cold sores to genital lesions to encephalitis; also a cause of fetal malformations and sepsis in early infancy.
- hertz (Hz)** Cycles per second; a measure of the frequency of sound.
- heteroplasmy** The presence of multiple kinds of mitochondrial DNA within a single cell or individual.
- heterotopia** Migration and development of normal neural tissue in an abnormal location in the brain.
- heterozygous** Carrying two genes that are dissimilar for one trait.
- hexosaminidase** An enzyme, a deficiency of which leads to Tay-Sachs disease.
- HIE** *See* hypoxic ischemic encephalopathy.
- high-stakes testing** One of the most controversial tenets of the No Child Left Behind (NCLB) Act of 2001. Under NCLB, all students, in all schools, in all districts must take standardized assessments to determine whether they are functioning on grade level in the areas of reading/language arts, math, and science, regardless of disability.
- high-tech assistive technology** A form of assistive technology that is complicated and often expensive to own and maintain.
- hippocampus** A region of the brain in the floor of each lateral ventricle that has a central role in the formation of memories, emotion, and the rapid learning of new information.
- hippotherapy** The therapeutic use of horseback riding.
- Hirschsprung disease** Congenitally enlarged colon.
- HMD** *See* hyaline membrane disease.
- holoprosencephaly** A congenital defect manifest by impaired cleavage of the cerebral hemispheres. *See* Appendix B.
- homeobox (HOX)** A group of genes involved in early embryonic development.
- homeostasis** Metabolic equilibrium of the body.
- homozygous** Carrying identical genes for any given trait.
- HOX** *See* homeobox.
- HSV** *See* herpes simplex virus.
- human chorionic gonadotropin (hCG)** The hormone secreted by the embryo that prevents its expulsion from the uterus. A pregnancy test measures the presence of this hormone in the blood or urine.
- hyaline membrane disease (HMD)** A disorder characterized by respiratory distress in the newborn period, principally in premature infants; *also called* respiratory distress syndrome (RDS).
- hybrid** Offspring of parents of different species.
- hydrocephalus** A condition characterized by the abnormal accumulation of cerebrospinal fluid within the ventricles of the brain. In infants, this leads to enlargement of the head and compression of the brain.
- hyperacusis** Unusual sensitivity to certain sounds such as a vacuum cleaner, often found in children with autism.
- hyperalimentation** *See* parenteral feeding.
- hyperbaric oxygen therapy (HBOT)** Involves breathing 100% oxygen while under increased atmospheric pressure.
- hyperbilirubinemia** Excess accumulation of bilirubin in the blood, which can result in jaundice, a yellowing of the complexion and/or the whites of the eyes, or kernicterus, the yellow staining of certain central parts of the brain.
- hypercholesterolemia** Elevated cholesterol levels in blood.
- hyperglycemia** High blood sugar level as seen in diabetes.
- hyperimmune globulin** Blood that is especially rich in antibodies against a virus.
- hyperkalemia** Elevations in levels of potassium in the blood.
- hyperopia** Farsightedness.
- hyperparathyroidism** High level of blood parathyroid hormone, which causes abnormalities in calcium and phosphorous metabolism.
- hyperphagia** Pathological overeating.
- hyperreflexia** Increased deep tendon reflexes, such as the knee jerk.
- hypersynchronous** In the context of the central nervous system (CNS), pertaining to the discharge of many neurons at the same time that leads to a seizure.
- hypertelorism** Widely spaced eyes.
- hypertension** Elevated blood pressure.
- hyperthermia** Significantly elevated body temperature.
- hyperthyroidism** Condition resulting from excessive production of thyroid hormone.
- hypertonia** Increased muscle tone as seen in spastic cerebral palsy.
- hypertrichosis** Excessive hair growth.
- hypertrophy** Overgrowth of a body part or organ.
- hypocalcemia** Low blood calcium level.
- hypogenitalism** Having small genitalia.
- hypoglycemia** Low blood sugar level, usually below a concentration of 40–50 milligrams of glucose per 100 milliliters of blood for a period of time.
- hypogonadism** Decreased function of sex glands with resultant retarded growth and sexual development.
- hypomania** Symptoms not severe enough to meet full mania criteria, with being silly not euphoric, talking fast or too much but not pressured, and babbling incoherently.
- hypopharynx** The area at the back of the throat where the larynx sits next to the entrance to the esophagus.
- hypoplasia** Defective formation of a tissue or body organ leading it to be small and underdeveloped.
- hypoplastic lungs** Small lungs that are not fully developed.
- hyporeflexia** Decreased deep tendon reflexes.
- hypospadias** A congenital defect in which the opening of the urethra is on the underside, rather than at the end, of the penis.

- hypotelorism** The presence of an abnormally decreased distance between the two eyes.
- hypotension** Low blood pressure.
- hypothalamus** A portion of the brain that directs a number of important bodily functions including many autonomic functions of the peripheral nervous system. Connections with structures of the endocrine and nervous systems enable the hypothalamus to play a vital role in maintaining homeostasis. The hypothalamus also influences various emotional responses.
- hypothermia** Excessively low body temperature.
- hypothyroidism** Condition resulting from deficient production of thyroid hormone.
- hypotonia** Decreased muscle tone.
- hypoxemia** Seriously low blood oxygen supply to the entire body.
- hypoxia** A lower-than-normal concentration of oxygen in blood.
- hypoxia-ischemia** Lack of adequate oxygenation and/or blood circulation.
- hypoxic** Having reduced oxygen content in body tissues.
- hypoxic ischemic encephalopathy (HIE)** An acute brain malfunction often resulting in coma caused by acute reduction in the blood flow and the oxygen supply to the brain.
- hypsarhythmia** Electroencephalographic (EEG) abnormality seen in infants with infantile spasms. It is marked by chaotic spike-wave activity.
- hysterectomy** The surgical removal of the uterus.
- Hz** See hertz.
- ichthyosis** Dry and scaly skin.
- ictal** Pertaining to a seizure event.
- IDDM** See insulin-dependent diabetes mellitus.
- idiopathic** Without an identifiable cause.
- IEP** See individualized education program.
- IFSP** See individualized family service plan.
- IH** See learning/instructional hierarchy.
- ileostomy** A surgically placed opening from the small intestine through the abdominal wall to divert bowel or bladder contents after an operation.
- ileum** Lower portion of the small intestine.
- imaginative play** When a child uses their imagination to make believe with role-play scenarios.
- imitation training** A behavior management technique in which the teacher demonstrates the desired behavior, asks the child to complete the action, and provides positive reinforcement when the task is completed.
- immunoglobulin** An antibody produced by the body after exposure to a foreign agent, such as a virus.
- impact** In reference to traumatic head injury, the forcible striking of the head against an object.
- imperforate** Lacking a normal opening in a body organ. The most common example in childhood is an absent or closed anus.
- implantation** The attachment and imbedding of the fertilized egg (blastocyst) into the mucous lining of the uterus.
- implicit bias** Attitudes or stereotypes that affect our understanding, actions, and decisions in an unconscious manner and may be favorable or unfavorable toward a particular social group.
- in utero** Occurring during fetal development.
- in vitro fertilization** Fertilization of harvested eggs and allowing them to develop in culture to the blastomere, or eight-cell stage, at which point they are implanted into the uterus of the recipient.
- inborn error of metabolism** An inherited enzyme deficiency leading to the disruption of normal bodily metabolism (e.g., phenylketonuria [PKU]). See Chapter 16.
- incidence** The rate of occurrence of new cases of a disorder in a population expressed as a function of time.
- incidental teaching** An ardent attempt to catch the child complying with commands or following instructions in his or her everyday life and to praise (reinforce) the performance.
- incisors** Front teeth used for cutting.
- incus** One of the three small bones in the middle ear that help amplify sound.
- independent residential alternatives (IRA)** Independent living centers; group homes designed for one to three individuals.
- indirect assessment** Simplest method of gathering information about behavioral function that consist of questionnaires and rating scales that are completed by caregivers.
- individualized education program (IEP)** A written plan, mandated by federal law, that maps out the objectives and goals that a child receiving special education services is expected to achieve over the course of the school year.
- individualized family service plan (IFSP)** A written plan detailing early intervention and related services to be provided to an infant or toddler with disabilities in accordance with federal law.
- inertial** Pertaining to the tendency to keep moving in the same direction as the force that produced the movement.
- infantile spasms** A seizure type in infancy marked by brief flexor spasms, usually lasting 1–3 seconds.
- infarction** Obstruction of the blood supply to an organ or region of tissue causing death of the tissue.
- inferior** In anatomy, below.
- inferior vena cava** The main vein feeding into the baby's heart.
- influenza** An acute illness caused by a virus that attacks the respiratory tract.
- informed consent** The written consent of a person to undergo a procedure or treatment after its risks and benefits have been explained in easily understood language.
- inhaled nitric oxide (iNO)** A therapeutic gas for treating persistent pulmonary hypertension of the neonate (PPHN). It is mixed with the baby's oxygen supply in miniscule amounts and directly stimulates pulmonary function.

- inner ear** Comprised of the semicircular canals and cochlea, which form the organs of balance and hearing and are embedded in the temporal bone of the skull.
- instructional training** A behavior management technique in which the teacher describes the desired behavior, asks the child to perform it, and provides positive reinforcement upon completion of the task.
- insulin-dependent diabetes mellitus (IDDM)** A disorder in which blood sugar level is high enough to require treatment with insulin.
- insult** An attack on a body organ that causes damage to it. This may be physical, metabolic, immunological, or infectious.
- integrative medicine** Refers to a practice that combines conventional and types of complementary and alternative treatments for which there is evidence of safety and effectiveness.
- intellectual disability** Significantly subaverage general intellectual functioning accompanied by significant limitations in adaptive functioning; *previously called* mental retardation. *See* Chapter 14.
- intensity** Strength.
- interictal** In an individual with a seizure disorder, pertaining to the periods when seizures are not occurring.
- internal capsule** The area of white matter in the brain that separates the caudate nucleus and the thalamus from the lenticular nucleus. The internal capsule contains both ascending and descending axons so it can control distant movement.
- interpersonal psychotherapy (IPT)** A time-limited psychotherapy that focuses on building interpersonal skills.
- interphase** The period in the cell life cycle when the cell is not dividing.
- interval schedules** Provision of reinforcement based on the passage of a certain amount of time relative to the child's performance of a behavior or task.
- intervillous space** the space between the villi of the placenta containing the vessels of both mother and embryo.
- intrathecal** The infusion of medication into the spinal space.
- intrauterine growth restriction (IUGR)** Fetal weight that is below the 10th percentile for gestational age as determined through an ultrasound; *also called* fetal growth restriction or small for gestational age.
- intravenous** Infusion into a vein.
- intraventricular hemorrhage (IVH)** A hemorrhage into the cerebral ventricles.
- introns** The noncoding regions of the genome.
- intubation** Insertion of a tube through the nose or mouth into the trachea to permit mechanical ventilation.
- inversion** In genetics, the result of two breaks on a chromosome followed by the reinsertion of the missing fragment at its original site but in the inverted order.
- ionic** Pertaining to mineral ions, a group of atoms carrying a charge of electricity.
- iris** The circular, colored membrane behind the cornea that surrounds the pupil.
- ischemia** A decreased blood flow to an area of the body that leads to tissue death.
- isochromosome** A chromosome with two copies of one arm and no copy of the other.
- isometric contraction** Muscular contraction against resistance in which the length of the muscle remains the same.
- ITP** *See* individualized transition plan.
- IUGR** *See* intrauterine growth restriction.
- IVH** *See* intraventricular hemorrhage.
- J tube** *See* jejunostomy tube.
- Jacksonian seizure** Spread of focal epileptiform activity to contiguous brain areas resulting in a seizure which starts in one part of the body and involves adjacent body regions as the seizure evolves.
- jaundice** A yellowing of the complexion and the whites of the eyes resulting from hyperbilirubinemia.
- jejunostomy (J) tube** A tube placed through the skin of the abdomen and directly into the jejunum to provide nutrition.
- jejunum** The second portion of the small intestine.
- joint attention** A precommunication skill in which an adult and a young child share gestures and eye gaze toward the same object or event. This skill is lacking in the young child with autism spectrum disorder.
- kangaroo care** A method of caring for premature babies in which the infants are held skin-to-skin with the mother throughout the day.
- karyotyping** Photographing the chromosomal makeup of a cell. In a human, there are 23 pairs of chromosomes in a normal karyotype.
- kernicterus** A disorder caused by severe jaundice in the newborn, with deposition of the pigment bilirubin in the brain leading to athetoid cerebral palsy, hearing loss, vision problems, and/or intellectual disability.
- ketogenic diet** Special diet high in fat used to promote the use of ketones as an energy source; used in some children with intractable epilepsy.
- ketosis** The buildup of acid in the body, most often associated with starvation, inborn errors of metabolism, or diabetes.
- Klebsiella pneumoniae** A bacteria that can cause pneumonia, especially in immunocompromised individuals.
- kyphoscoliosis** A combination of humping and curvature of the spine.
- kyphosis** An excessive anterior (forward) curvature of the spine creating a hump.
- labyrinth** One of the major components of the inner ear, the other being the cochlea.
- lactase** Enzyme necessary to digest the milk sugar lactose.
- lactic acid** Chemical produced in muscles as a result of anaerobic glucose metabolism.
- lacrimal gland** Gland that produces tears.
- lactose** Milk sugar composed of glucose and galactose.
- lamina** Layered.
- lanugo** Fine body hair found in newborns.

- large for gestational age (LGA)** Weighing more than 4 kilograms, about 9 or more pounds at birth. This typically occurs in infants of diabetic mothers.
- lateral** To the side; away from the midline.
- lateral ventricles** Cavities in the interior of the cerebral hemisphere containing cerebrospinal fluid. They are enlarged with hydrocephalus or with brain atrophy.
- laterality** Dominance of one side of the brain, eyes, or hands in controlling particular functions.
- law of effect** Functional relationship between behavior and its consequences.
- LBW** See low birth weight.
- learned helplessness** Occurs when families, teachers, and other well-intentioned people often protect youth with disabilities from making mistakes and avoid discussing the ramifications of a child's disability as they help them prepare for adulthood.
- learning disability** A developmental disability characterized by difficulty with certain academic skills such as reading or writing in individuals with typical intelligence. See Chapter 20.
- learning/instructional hierarchy (IH)** Describes behaviors to be learned and mastered, not only by their form but by the level of proficiency with which they are performed.
- left ventricular hypertrophy** Enlargement of the left side of the heart.
- lens** The biconvex, translucent body that rests in front of the vitreous humor of the eye and precisely focuses the light rays on the retina.
- lentiform nucleus** A large, cone-shaped mass of gray matter just lateral to the internal capsule of the brain.
- lesions** Injuries or loss of function.
- leukemias** Blood cell cancers.
- lexicon** The vocabulary of a person.
- LGA** See large for gestational age.
- ligament** A sheet or band of tough, fibrous tissue connecting bones or cartilage at a joint.
- ligamentous laxity** Double jointedness; hyperflexibility.
- linear fracture** Break of a bone in a straight line; refers to a type of skull fracture or fracture of a long bone (arm or leg).
- lipid metabolism** The creation and/or breakdown of lipids including cholesterol and fat-soluble vitamins.
- lipoma** A benign, fatty tissue tumor.
- lissencephaly** A congenital abnormality marked by a "smooth" brain due to incomplete neuronal proliferation and migration and resultant lack of folds (gyri) and grooves (sulci). See Appendix B.
- listeria monocytogenes** The causative agent of listeriosis.
- locus** Focus or location.
- lordosis** An excessive posterior (backward) curvature of the spine.
- low birth weight (LBW)** Term often used to describe an infant with a birth weight less than 2,500 grams (5 1/2 pounds).
- lower esophageal sphincter (LES)** The muscular valve connecting the esophagus and stomach and normally preventing reflux.
- low-tech assistive technology** An assistive device that does not require batteries or other electric sources to operate.
- lumbar** Pertaining to the lower back.
- lumbar puncture** The tapping of the subarachnoid space to obtain cerebrospinal fluid from the lower back region. This procedure is used to diagnose meningitis and to measure chemicals in the spinal fluid; *also called* a spinal tap.
- lumbosacral plexus** Nerves arising from the lower back enlargement of the spinal cord and controlling leg movement.
- lymphadenopathy** Enlargement of lymph nodes.
- lymphocyte** A type of white blood cell.
- lymphoma** A cancerous growth of lymphoid tissue.
- lyonization** The genetic principle discovered by Mary Lyon that there is X chromosome inactivation in females.
- lysosome** Minute organelle in cells that contains enzymes used to digest potentially toxic material.
- macrocephaly** Large head size.
- macroorchidism** Having abnormally large testicles; found in fragile X syndrome.
- macrosomia** Large body size.
- macrostomia** Large mouth.
- macula** The area of the retina that contains the greatest concentration of cones and the fovea centralis, where central vision is processed.
- magnetic resonance imaging (MRI)** Imaging procedure that uses the magnetic resonance of atoms to provide clear images of interior parts of the body. It is particularly useful in diagnosing structural abnormalities of the brain.
- magnetic resonance spectroscopy (MRS)** A study that can be done as part of a regular MRI scan. Rather than provide a picture of the brain, it analyzes the presence and amount of certain metabolic components in various brain regions. It is particularly helpful in diagnosing certain inborn errors of metabolism, such as mitochondrial disorders (see Appendix B).
- major depression** A prolonged period of depressed mood.
- malformations** Abnormally formed body parts.
- malignant hyperthermia** A life-threatening elevation of body temperature associated with the administration of an anesthetic agent.
- malleus** One of the three small bones in the middle ear that help amplify sound.
- malnutrition** Inadequate nutrition for typical growth and development to occur.
- malocclusion** The improper fitting together of the upper and lower teeth.
- mandible** Lower jaw bone.
- mania** A distinct period of abnormally and persistently elevated, expansive, or irritable mood. This mood disturbance is sufficiently severe to cause impairment in function.
- manic depression** See bipolar disorder.
- Marfan syndrome** Disorder of connective tissue that strengthens the body's structures (see Appendix B).

- mass spectrometry** A technique used for identifying chemical, drug, or metabolic abnormalities in the blood or urine.
- mastoiditis** Infection of the mastoid air cells that rest in the temporal bone behind the ear. This is an infrequent complication of chronic middle-ear infection.
- mature minor** A teenage minor who may give consent because the physician judges that he or she understands the nature, purpose, and risks of the proposed treatment; generally limited to minors at least 15 years old where the treatment is for the patient's own benefit and is judged necessary by conservative medical opinion (compare with *emancipated minor*).
- maxilla** The bony region of the upper jaw.
- maxillary hypoplasia** Incomplete development of the upper jaw.
- MBD** See metabolic bone disease.
- meconium** The thick and tarry stool that is formed during fetal life consisting of swallowed amniotic fluid debris, gastrointestinal mucous and green bile secretions from the liver, and sloughed off gastrointestinal epithelial cells; is not normally passed until after birth.
- medial** Toward the center or midline.
- median plane** The midline plane of the body. It runs vertically and separates the left and right halves of the body.
- medical assistive technology** Subset of assistive technology that is used for primarily medical or life-sustaining reasons (e.g., ventilators and feeding pumps).
- medical home** Involves a trusting partnership between a child, a child's family, and the pediatric primary care team who oversees the child's health and well-being within a community-based system that provides uninterrupted care to support and sustain optimal health outcomes.
- medication reconciliation** The process of creating an accurate list of all the medications a patient is taking and comparing that list against the physician's admission, transfer, and/or discharge orders to ensure that both match.
- medium chain fatty acids** Fatty acids that can bypass the normal uptake process and go directly to the liver.
- medulloblastomas** Cerebellar tumors.
- megavitamin therapy** The use of more than 10 times the average daily required amount of vitamins; *also called* orthomolecular therapy.
- meiosis** Reductive cell division occurring only in eggs and sperm in which the daughter cells receive half (23) the number of chromosomes of the parent cells (46).
- melanocytes** Pigment-forming skin cells.
- melatonin** A naturally occurring hormone available as an over-the-counter preparation for which there is evidence of efficacy in improving sleep onset in children with disabilities who have sleep problems.
- Mendelian traits** Dominant and recessive traits inherited according to the genetic principles put forward by Gregor Mendel.
- meningeal** Related to the meninges, the three membranes enveloping the brain and spinal cord.
- meningitis** Infection, often bacterial, of the meninges or sac that surround the brain.
- meningocele** Protrusion of the meninges through a defect in the skull or vertebral column; a neural tube defect.
- meningoencephalitis** A generalized and often devastating infection of the brain and central nervous system.
- meningomyelocele** Protrusion of meninges and malformed spinal cord through a defect in the vertebral column; *also called* myelomeningocele.
- menses** Menstrual flow.
- mental retardation** See intellectual disability.
- mentation** Thinking.
- mesencephalon** Midbrain region.
- mesial temporal sclerosis** Scarring in the middle temporal lobes of the brain often leading to partial seizures. See Chapter 22.
- mesoderm** Middle cell layer in the embryo.
- messenger ribonucleic acid (mRNA)** RNA, synthesized from a DNA template during transcription, that mediates the transfer of genetic information from the cell nucleus to ribosomes in the cytoplasm, where it serves as a template for protein synthesis.
- metabolic bone disease (MBD)** *Previously called* renal osteodystrophy, results from abnormalities in calcium, phosphorous, vitamin D, and parathyroid hormone.
- metaphase** The stage in cell division in which each chromosome doubles.
- metaphyses** The ends of the shaft of long bones connected to the epiphyses.
- methionine** An amino acid.
- methylation** The attachment of methyl groups to DNA at the cytosine base that turns gene function off.
- microboard** A non-profit corporation, usually of family members and friends of a person with a disability, created to support that person.
- microcephaly** Abnormally small head.
- microdeletion** A microscopic deletion in a chromosome associated with a loss of a small number of contiguous genes; a chromosomal deletion spanning several genes that is too small to be detected under the microscope using conventional cytogenetic methods but can be detected using newer molecular genetic techniques such as microarrays.
- microdeletion syndromes** Genetic disorders caused by mutations in a small number of contiguous genes, an example being velocardiofacial syndrome; *see also* contiguous gene syndrome.
- microdontia** Very small teeth.
- micrognathia** Receding chin.
- microphthalmia** Small eye.
- micropremie** Term often used to describe an infant born weighing less than 800 grams (1.75 pounds) or before 26 weeks.
- microswitches** Switches used to control computers, environmental control systems, or power wheelchairs that have been adapted so that less pressure than normal is required for activation.

- microtia** Small ear.
- microtrauma** Small injuries such as stress cracks or fractures that occur in the growth area or cartilage of growing bones as a result of high impact or overloading.
- mid-tech assistive technology** An assistive device that generally requires battery/electrical power or is more complex in its use; for example, teletypewriter (TTY) devices for those who are deaf, home-infusion pumps, suction machines, and sophisticated manual wheelchairs.
- middle ear** The part of the ear that consists of the eardrum and, beyond it, a cavity ending in a chain of three little bones that connect the middle ear to the internal ear.
- MII** See multiple intraluminal impedance.
- milligram** One thousandth of a gram.
- milliliter** One thousandth of a liter; equal to about 15 drops.
- mindfulness practice** The psychological process of bringing one's attention to the internal and external experiences occurring in the present moment, which can be developed through the practice of meditation or other training.
- missense mutation** Gene error (mutation) resulting from the replacement of a single nucleic acid for another, resulting in a misreading of the DNA code.
- mitochondrial myopathy** Congenital muscle disorder caused by a mutation in the mitochondrial DNA.
- mitosis** Cell division in which two daughter cells of identical chromosomal composition to the parent cell are formed. Each contains 46 chromosomes.
- mixed cerebral palsy** A form of cerebral palsy with spastic and dyskinetic components; this term is used when more than one type of motor pattern is present and when one pattern does not clearly predominate over another.
- MOs** See motivating operations.
- modification** In special education, a substantial change in the method or scoring scale used to assess a student's academic performance or knowledge (e.g., using a portfolio of work to demonstrate a student's learning).
- molded ankle-foot orthoses** A plastic insert for the shoe that is used to treat toe walking.
- monosomy** Chromosome disorder in which one chromosome is absent. The most common example is Turner syndrome, XO (see Appendix B).
- monosomy X** Turner syndrome (see Appendix B).
- morbidity** Medical complication of an illness, procedure, or operation.
- moro reflex** A primitive reflex elicited when a newborn infant experiences a sudden drop of the head and neck or a loud noise. The infant responds with sudden extension and then flexion of the neck, arms, and legs, and then cries irritably.
- morphemes** The smallest linguistic units of meaning.
- morula** The group of cells formed by the first divisions of a fertilized egg.
- mosaic trisomy** Type of Down syndrome in which the individual has two distinct populations of cells, one containing 46 chromosomes and the other containing 47 chromosomes.
- mosaicism** The presence of two genetically distinct types of cells in one individual.
- MOSF** See multi-organ system failure.
- motivating operations (MOs)** Play a central role in the operant learning conceptualization of motivation; produces two effects: 1) a change in the value of a consequence and 2) a corresponding change in the strength of motivation.
- motor point block** The injection of a denaturing agent into the nerve supply of a spastic muscle. This effectively interrupts the nerve supply at the entry site to a spastic muscle without compromising sensation and results in the return of tone toward normal.
- MRI** See magnetic resonance imaging.
- mRNA** See messenger ribonucleic acid.
- MRS** See magnetic resonance spectroscopy.
- MS/MS** See tandem mass spectrometer.
- mucopolysaccharides** Product of metabolism that may accumulate in cells and cause a progressive neurological disorder (e.g., Hurler syndrome, see Appendix B).
- multidisciplinary** When referring to developmental disabilities, this term describes an approach involving several professional specialties who assess a patient together and develop/carry out a treatment plan.
- multifactorial** Describing an inheritance pattern in which environment and heredity interact.
- multi-organ system failure (MOSF)** This devastating condition can result from the diving reflex during severe hypoxic ischemic encephalopathy (HIE).
- multiple intraluminal impedance (MII)** A technology that measures the movement of fluids, solids, and air in the esophagus.
- multitiered systems of support (MTSS)** A systemic, continuous improvement framework in which data-based problem-solving and decision making is practiced across all levels of the educational system for supporting students.
- muscle spindles** Muscle fibers that are part of the reflex arc that controls muscle contraction.
- muscle and tendon structures** Muscle and tendons associated with long bones such as the tibia, fibia, and femur that are more susceptible to injury during growth periods.
- musculoskeletal** Referring to the muscle and bone support system of the body.
- mutation** A change in the genomic sequence resulting in a variant form that may be transmitted to subsequent generations and may be associated with disease.
- myasthenia gravis** Neuromuscular disorder involving the muscles and the nerves that control them (see Chapter 9).
- myelinated** Insulating sheath around many nerve fibers in the white matter, increasing the speed at which impulses are conducted.
- myelination** The production of a coating called myelin around an axon, which quickens neurotransmission; a

- process that involves elaboration of supportive structures that improve transmission of electrical impulses from one part of the nervous system to another.
- myelomeningocele** *See* meningomyelocele.
- myoclonus** Irregular, involuntary contraction of a muscle.
- myoglobinuria** The spillage of myoglobin, the oxygen-transporting protein of muscle, into the urine. This can occur with trauma, vascular problems, certain drugs and other situations that destroy or damage the muscle, releasing myoglobin into the circulation and thus to the kidneys.
- myopathies** A muscular disease in which the muscle fibers do not function for any one of many reasons, resulting in muscular weakness. The most common example is muscular dystrophy.
- myopia** Nearsightedness.
- myosin** Protein necessary for muscle contraction.
- myotonia** Abnormal rigidity of muscles when voluntary movement is attempted.
- myringotomy** The surgical incision of the eardrum, usually accompanied by the placement of pressure-equalization tubes, to drain fluid from the middle ear.
- nasal cannula** A plastic prong placed in the nose and connected to a tube that delivers an oxygen/air mixture.
- nasal pillows** A prop attached to an oxygen line to permit the flow of oxygen directly into the nose.
- nasogastric (NG) tube** A feeding tube placed in the nose and extended into the stomach.
- nasojejunal tube** A feeding tube placed in the nose and extended through the stomach and into the jejunum.
- nasopharynx** Posterior portion of the oral cavity above the palate.
- NCS** *See* nerve conduction studies.
- NDT** *See* neurodevelopmental therapy.
- NEC** *See* necrotizing enterocolitis.
- necrosis** Death of tissue.
- necrotizing enterocolitis (NEC)** Severe inflammation of the small intestine and colon, most common in premature infants.
- negative punishment** Involves the contingent removal of a consequence (i.e., positive reinforcer).
- negative reinforcement** Behavioral phenomenon in which an individual's behavior permits an unpleasant event to be avoided or escaped, with a resultant increase in this behavior in the future.
- neonatal intensive care unit (NICU)** Hospital unit specializing in providing newborn life support treatments.
- neonatal seizure** Seizures in newborn infants appear different than in older children. The seizure may manifest as arm and/or leg tonic/clonic movements that seem like bicycling or rowing. Movements may also be more subtle, including spasmodic lip smacking or tongue thrusting, ocular movements such as excessive blinking or prolonged eye opening/staring, or episodes of apnea and bradycardia.
- nerve blocks** Direct injection of denaturing agents into motor nerves to decrease spasticity.
- nerve conduction studies (NCS)** Involves placing needle electrodes at various points on the body to test motor and sensory function of the peripheral nerves.
- nerve conduction velocity** Measure of nerve function.
- neuropores** The rostral and caudal openings of the neural tube which close around 6 weeks gestational age.
- neural crest** A band of cells that lie along the length of the neural tube and developing spinal cord.
- neural fold** During embryonic life, the fold created when the neural plate expands and rises; later it becomes the spinal column.
- neural network** A network involving many brain regions working in concert to store and use information obtained from the environment.
- neural plate** Earliest fetal brain mass development derived from the ectodermal germ layer of the embryo in the first 7 weeks of gestation.
- neural proliferation** A sustained period of vigorous cellular division which peaks between 6 and 22 weeks gestational age, giving rise to precursors of the future neuronal and glial populations of the brain.
- neural tube** The stage of central nervous system (CNS) development that follows neural plate formation, which subsequently gives rise to the various parts of the brain (i.e., the forebrain folding into the cerebrum and the hindbrain into the cerebellum, brainstem, and spinal cord).
- neural tube defects (NTDs)** Birth defects of the brain and spina cord (i.e., spina bifida and anencephaly).
- neurocutaneous syndromes** A group of genetic disorders that lead to growth of tumors in various parts of the body.
- neurodevelopmental assessment** A comprehensive evaluation of brain systems including neuromotor, learning, attention, speech, language, motor planning, cognition, and behavior.
- neurodevelopmental treatment (NDT)** An intervention approach used with children with neurologically based motor disabilities such as cerebral palsy.
- neurofibromatosis** Genetic disorders associated with tumor formation in the brain and other organs. *See* Appendix B.
- neurogenesis** The birth of neurons.
- neurogenic** Originating in, starting from, or caused by the nervous system or nerve impulses.
- neurulation stage** The folding process in human embryos, which includes the transformation of the neural plate into the neural tube.
- neuroleptic malignant syndrome** A rare toxic reaction to a medication in which there is a potentially life-threatening high fever, most commonly a problem with anesthetic agents.
- neuromuscular** Affecting both muscles and nerves.
- neuron** Any of the impulse-conducting cells that constitute the brain, spinal column, and nerves, consisting of a nucleated cell body with one or more dendrites and a single axon; *also called* a nerve cell.
- neuronal** Pertaining to the neuron.

- neuroplasticity** The inherently dynamic biological capacity of the central nervous system to undergo maturation, to change structurally and functionally in response to experience, and to adapt following injury.
- neuropsychological assessment** The administration of a battery of tests to determine a patient's cognitive function.
- neuropsychology** The study of the structure and function of the brain as it relates to specific psychological processes and behaviors.
- neurotoxicant** A chemical compound that can damage neurons; *also called* neurotoxin.
- neurotransmitter** A chemical released at the synapse that permits transmission of an impulse from one nerve to another.
- neurulation** Sequential central nervous system developmental processes of neuron cell proliferation and the migration of nascent neurons outward from the center of the developing brain to the outer cortex.
- neutropenia** Low white blood cell count.
- next-generation sequencing (NGS)** A high-throughput method used to determine a portion of the nucleotide sequence of an individual's genome.
- NG tube** *See* nasogastric tube.
- NICU** *See* neonatal intensive care unit.
- nomogram** A mathematical model that shows relationships between things.
- nondisjunction** Failure of a pair of chromosomes to separate during mitosis or meiosis, resulting in an unequal number of chromosomes in the daughter cells.
- nonsense mutation** Gene defect in which a single base pair substitution results in the premature termination of a message and the resultant production of an incomplete and inactive protein; *See* missense mutation.
- nonverbal communication** The use of gestures, facial expressions, signs, and body positions to communicate.
- norepinephrine** A neurotransmitter.
- normalizing** Making conform to a norm or standard.
- NTDs** *See* neural tube defects.
- nuchal translucency measurement** The assessment of the size of the translucent space behind the neck of the fetus using ultrasound at between 10 and 14 weeks of pregnancy, reflecting the amount of fluid that has accumulated under the skin of the fetus. It is abnormal in Down syndrome.
- nucleotide bases** The nucleic acids that form DNA—adenine, guanine, cytosine, and thymine.
- nucleus** The spheroid body located centrally within a cell and containing the chromosomes.
- nutritive assistive devices** Devices that assist in providing nutrition to an individual who cannot take oral feeding. These include nasogastric and gastrostomy feeding tubes.
- nystagmus** Involuntary rapid movements of the eyes (jiggling of the eyes) due to abnormalities in the cerebellum.
- object permanence** In infant development the ability to understand that objects continue to exist even if they cannot be seen directly.
- oblique muscles** Eye muscles whose primary function is to rotate the eyes. Their secondary function is to handle moving the eyes horizontally and vertically.
- obsessions** Recurrent and persistent thoughts and ideas that cannot be suppressed.
- obsessive-compulsive disorder (OCD)** A psychiatric disorder in which recurrent and persistent thoughts and ideas that cannot be suppressed (obsessions) are associated with repetitive behaviors (compulsions), such as excessive handwashing.
- obstructive sleep apnea** Recurring brief interruption of breathing during sleep due to obstruction usually of the upper airway.
- obstructive uropathy** Pathologic condition that blocks urine flow.
- occipital lobe** The posterior area of the brain where the visual receptive cortex is located.
- OCD** *See* obsessive-compulsive disorder.
- ocular** Pertaining to the eye.
- oculomotor nerve** The third cranial nerve controls the four eye muscles not controlled by the trochlear and abducens nerves.
- off label** Use of medication for disorders that have not been FDA approved.
- oligodendrocytes** A type of glial brain cell.
- oligodontia** The absence of one or several teeth.
- oligohydramnios** The presence of too little amniotic fluid, which may result in fetal deformities, including clubfoot and hypoplastic lungs.
- oliguria** Decreased passage of urine.
- omphalocele** Congenital herniation of abdominal organs through the navel.
- onychomycosis** A fungal infection of the nails.
- oophorectomy** Surgical removal of the ovary or ovaries.
- operant control** Control established and maintained by operant contingencies (i.e., the relationships in effect between the behavior and its consequences).
- ophthalmologist** Physician specializing in treatment of diseases of the eye.
- ophthalmoscope** An instrument containing a mirror and a series of magnifying lenses used to examine the interior of the eye.
- opiate antagonists** A category of medications that block endorphin receptors of the brain.
- opisthotonos** Abnormal positioning of the body in which the back is arched while the head and feet touch the bed; holding the head arched backward.
- optic chiasm** Located just before the nerves enter the brain, it is where the crossover of nerve fibers occurs.
- optic nerve** Transmits visual information from the retina to the brain.
- optokinetic** Pertaining to movement of the eyes.
- oral pharyngeal musculature** Muscles in the throat.
- oral preparatory phase (phase I)** The step preceding swallowing in which food is formed into a bolus in the mouth.
- oral transport (phase II)** The transport of a bolus of food to the back of the mouth so that it can be swallowed; primarily under volitional control.

- organ of Corti** A series of hair cells in the cochlea that form the beginning of the auditory nerve.
- organelles** Small, specialized structures within cells that operate like organs by carrying out specific tasks. Examples include the nucleus, which contains the chromosomes, and mitochondria, which are essential for energy production.
- organic acidemias** Inborn errors of metabolism involving enzyme deficiencies in the breakdown of organic acids (e.g., methylmalonic aciduria; *see* Appendix B); *also called* organic acid disorders and organic acidurias.
- organophosphate pesticides** Any of several organic compounds containing phosphorus that are used as pesticides.
- ornithine transcarbamylase** An enzyme in the urea cycle. An inborn error of metabolism involving a deficiency of this enzyme leads to episodes of encephalopathy.
- orocutaneous stimulation** This stimulation therapy mimics the temporal organization of sucking and can enhance the premature infant's acquisition of a functional suckle pattern.
- oropharynx** The part of the pharynx between the soft palate and the upper edge of the epiglottis.
- orthographic** Relating to the rules that let us visually represent a language correctly.
- orthomolecular therapy** *See* megavitamin therapy.
- orthopedic** Relating to bones or joints.
- orthosis** Orthopedic device (e.g., a splint or brace) used to support, align, or correct deformities or to improve the function of limbs; *plural*: orthoses; *also called* orthotic.
- orthotic** Device that supports or corrects the function of a limb or the torso; *also called* orthosis.
- orthotist** Professional trained in the fitting and construction of splints, braces, and artificial limbs.
- osmolarity** The concentration of dissolved particles in a liquid.
- ossicles** The three small bones in the middle ear—the stapes, incus, and malleus.
- osteoarthritis** Degenerative joint disease.
- osteoblasts** Cells that produce bony tissue.
- osteoclast** Cell that absorbs and removes bone.
- osteoid** The substrate of bone.
- osteomyelitis** Bone infection.
- osteopenia** The loss of bony tissue resulting in low bone density.
- osteopetrosis** A genetic disorder marked by deficient osteoclastic activity. A buildup of bone encroaches on the eye, brain, and other body organs, leading to early death; bone weakness.
- osteotomies** Surgical cuts through the bone to correct deformities.
- ostomy** An artificial opening in the abdominal region, for example, for discharge of stool or urine.
- otitis media** Middle-ear infection.
- otoacoustic emissions (OAE)** Low-intensity sound energy emitted by the cochlea subsequent to sound stimulation as measured by a microphone coupled to the external ear canal.
- otolith organ** Part of the ear that contains both the organ of hearing (the cochlea) and the organ of balance (the labyrinth).
- ototoxic** Toxic to the auditory nerve, leading to hearing impairment.
- oval window** Connects the middle to the inner ear.
- overt strokes** Involves a focal (localized) neurological deficit that lasts more than 24 hours and results from an occlusion of one of the large anterior cerebral circulation vessels.
- oxidative phosphorylation** A chemical reaction occurring in the mitochondrion, resulting in energy production.
- oximeter** An instrument that measures oxygen saturation in the bloodstream.
- oxygen saturation** The amount of oxygen bound to hemoglobin in the blood, expressed as a percentage of the maximal binding capacity. The normal range is 95%–100%.
- oxygenation** The provision of sufficient oxygen for bodily needs.
- pachygyria** Abnormal convolutions on the surface of brain.
- palatal** Relating to the palate, the back portion of the roof of the mouth.
- palate** The roof of the mouth.
- pallid infantile syncope** Form of breath-holding spell in which the child turns pale and faints follows a frightening or painful experience.
- palmar grasp reflex** A primitive reflex where when an object is placed in an infant's hand and the palm of the child is stroked, the fingers will close reflexively.
- pancreatitis** An inflammation of the pancreas.
- panic disorder** A psychiatric disorder in which the patient has episodes of sudden and irrational fears associated with hyperventilation and palpitations.
- Panayiotopoulos syndrome** Also known as early-onset occipital epilepsy; is a common childhood epilepsy syndrome with partial seizures.
- parallel play** Involves children playing adjacent to each other but not trying to influence one another's behavior. Children usually play alone during parallel play but are interested in what other children are doing. This usually occurs after the first birthday.
- paraplegia** Paralysis of the legs and lower body.
- parapodium** A reciprocal gait orthosis or a hip-knee-ankle-foot orthosis used in combination with crutches or a walker.
- parasomnia** Sleep disturbances (i.e., night terrors and sleep walking).
- parenchymal** Tissue within a body organ.
- parent-child interaction therapy (PCIT)** A psychological treatment approach for young children with emotional and behavioral disorders that places emphasis on improving the quality of the parent-child relationship and changing parent-child interaction patterns. Children and their caregivers are seen together in PCIT.
- parenteral feeding** Intravenous provision of high-quality nutrition (i.e., carbohydrates, protein, and fat) used in children with malabsorption, malnutrition, and

- short bowel syndrome; *also called* hyperalimentation; parenteral feeding is usually administered in a hospital setting on a short-term basis.
- parenting networks** Parents who educate and support one another.
- paresthesias** Numbness with skin sensations, such as burning, prickling, itching, or tingling.
- parietal lobe** The middle-upper part of the hemisphere of the brain; brain region involved in integrating sensory information and in visual-spatial processing.
- Parkinson's disease** A progressive neurological disease, usually occurring in older people, associated with tremor, slowed movements, and muscular rigidity.
- parotid** The salivary gland beside the ear.
- paroxysmal** Intermittent.
- partial graduated guidance** Instructor uses minimal physical contact but much praise in helping the child learn a desired task.
- parvovirus** A group of extremely small DNA viruses. Intrauterine infection with one type of parvovirus increases the risk of miscarriage but has not been shown to result in fetal malformations.
- patella** Kneecap.
- patent ductus arteriosus (PDA)** The persistence of a fetal passage permitting blood to bypass the lungs.
- patent foramen ovale (PFO)** A tiny open window in the atrial wall of the heart passing oxygenated blood from the right atrium into the left atrium, thus bypassing circulation to the fetal lungs *in utero*.
- paternalism** Imposing a decision on another person for that person's welfare (e.g., the theory that "doctor knows best").
- PBIS** *See* positive behavior interventions and supports.
- PCB** *See* polychlorinated biphenyl.
- PDA** *See* patent ductus arteriosus.
- PDD** Pervasive developmental disorder (*see* Chapter 18).
- penetrance** The percentage of people with a particular genetic mutation who express symptoms of the disorder. A disorder shows reduced penetrance when some people with the genetic defect are completely without symptoms.
- percutaneous umbilical blood sampling (PUBS)** A prenatal diagnostic procedure for obtaining fetal blood for genetic testing; *also called* cordocentesis.
- percutaneously** Through the skin.
- perfusion** The passage of blood through the arteries to an organ or tissue.
- perinatal transmission** Refers to the transmission of a disease-causing agent from mother to baby during the period immediately before and after birth.
- periodontal disease** Disease of the gums and bony structures that surround the teeth.
- periosteum** Fibrous tissue covering and protecting all bones.
- peripheral nervous system** The parts of the nervous system other than the brain and spinal cord.
- peripheral venous lines** Catheters that are placed in a superficial vein of the arm or leg to provide medication.
- peristalsis** The voluntary constriction and relaxation of the muscles of the esophagus and intestine, creating wavelike movements that push food forward.
- peritoneal** Referring to the membrane surrounding the abdominal organs.
- periventricular leukomalacia (PVL)** Injury to part of the brain near the ventricles caused by lack of oxygen; occurs principally in premature infants.
- periventricular region** The area surrounding the ventricles.
- peroxisome** A cellular organelle involved in processing fatty acids.
- persistent pulmonary hypertension of the newborn/persistent fetal circulation (PPHN/PFC)** Persistent high pulmonary blood pressure in the newborn period due to vasoconstriction of the pulmonary arterial blood vessels and resulting in severe hypoxia.
- pes cavus** High-arched foot.
- pes planus** Flat feet.
- pesticide** A chemical used to kill insects.
- PET scan** *See* positron emission tomography.
- petechiae** A small purplish spot, usually on the skin, caused by a minute hemorrhage.
- PFO** *See* patent foramen ovale.
- PGD** *See* preimplantation genetic diagnosis.
- pH probe** A small sensor, which detects the pH, or acidity, above the gastroesophageal junction.
- phakomatoses** Genetic syndromes characterized by benign tumor like nodules of the eye, skin, and brain. The four disorders designated phakomatoses are neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome, and von Hippel-Lindau disease.
- phalanges** Bones of the fingers and toes.
- pharmacodynamics** Explains the drug's effects (i.e., the relationship between the dose of a drug and the individual's response to it).
- pharmacogenomics** The study of how variations in the human genome affect the individual's response to a particular medication or group of medication.
- pharmacokinetics** The interactions of a drug and the body in terms of its absorption, distribution, metabolism, and excretion.
- pharyngeal** Pertaining to the pharynx or back of the throat.
- pharyngeal transfer phase (phase III)** The transfer of a food bolus from the mouth to the pharynx on its way to being swallowed; begins when the bolus passes the faucial arches (near the tonsils) and triggers the start of the swallowing cascade.
- pharynx** The back of the throat.
- phenothiazines** Antipsychotic medications that affect neurochemicals in the brain and are used to control aggressive behavior and psychotic symptoms.
- phenotype** The physical appearance of a genetic trait.
- phenylalanine** An amino acid, the elevation of which causes phenylketonuria (PKU).
- phenylketonuria (PKU)** Birth defect in which a child is born without the ability to break down amino acids called phenylalanine. *See* Chapter 16.

- philtrum** Vertical groove between nose and mouth.
- phobias** Irrational fears.
- phocomelia** Congenitally foreshortened limbs.
- phoneme** The smallest unit of sound in speech.
- phonetic** Pertaining to the sounding out of words.
- phonological disorder** Involves having difficulty learning the sound system of a language and the rules for combining sounds.
- phonological processing** The use of the sounds of one's language (i.e., phonemes) to process spoken and written language.
- phonological processing disorder** A developmental disorder in which there is difficulty learning the rules about which sounds go together in specific positions within words when sounds are voiced or voiceless.
- phonology** The set of sounds in a language and the rules for using them.
- photic** Relating to light.
- photoreceptors** Receptors for light stimuli; the rods and cones in the retina.
- physes** Growth plates of a developing long bone.
- physiotherapy** Physical therapy.
- pica** Ingestion of nonfood items.
- pincer grasp** A pattern emerging at 10–12 months of age whereby an infant can hold a small object between the pads of the opposed thumb and index or middle finger.
- pitch** The frequency of sounds, measured in cycles per second, or hertz (Hz). Low-pitched sounds have a frequency less than 500 Hz and a bass quality. High-pitched sounds have a frequency greater than 2,000 Hz and a tenor quality.
- PKU** See phenylketonuria (see Chapter 16 and Appendix B).
- placebo** An inactive substance used as a control in a study to determine the effectiveness of a drug.
- placebo response** A situation where an inactive substance (e.g., sugar, distilled water, or saline solution) improves a patient's condition simply because the person has the expectation that it will be helpful.
- placenta** The organ of nutritional exchange between the mother and the embryo. It has both maternal and embryonic elements, is disc shaped, and is about 7 inches in diameter. The umbilical cord attaches in the center of the placenta; *also called* the afterbirth; *adjective*: placental.
- placenta accreta** Abnormal adherence of the chorionic villi to the uterus.
- placenta previa** Condition in which the placenta is implanted in the lower segment of the uterus, extending over the cervical opening.
- placental abruption** See abruptio placenta; early separation of the placenta from the uterine wall.
- planned ignoring** A behavior management technique based on withholding positive reinforcement following the occurrence of a nondangerous, nondestructive challenging behavior; *also called* extinction.
- plantarflexion** A toe-down motion of the foot at the ankle.
- plantargrade** Flat on the floor.
- plaque** A semi-hardened accumulation of bacteria adhering to the teeth.
- plasma** The noncellular content of blood; *also called* serum.
- plasmapheresis** The removal of blood followed by filtering the plasma and reinfusing the blood products. This procedure is done to remove toxins and antibodies as in Guillain-Barré syndrome.
- plasticity** The ability of an organ or part of an organ to take over the function of another damaged organ; the ability of the nervous system to change or adapt.
- pneumocystis carinii pneumonia** Lung infection often seen in immunocompromised individuals, such as those with acquired immunodeficiency syndrome (AIDS).
- point mutation** A mutation in a single nucleotide (DNA) base leading to a genetic syndrome (e.g., sickle cell disease).
- polar body testing** Polar bodies are the by-products of the egg's division during meiosis. The two polar bodies are essentially discarded by the egg. By analyzing the polar bodies, it is possible to infer the genetic status of the egg.
- polio** Viral infection of the spinal cord causing an asymmetrical ascending paralysis, now prevented by vaccination.
- polychlorinated biphenyl (PCB)** One of a group of organic compounds originally used in industry and now recognized as an environmental pollutant.
- polydactyly** Extra fingers or toes.
- polygenic risk score (PRS)** A number based on the variation in multiple genetic loci that serves as a predictor of the risk of developing a specific polygenic disorder such as hypertension.
- polyhydramnios** The presence of excessive amniotic fluid; often associated with certain fetal anomalies such as esophageal atresia.
- polymicrogyria** A brain with too many convoluted gyri that are smaller than normal due to abnormal neuronal migration during embryogenesis of the central nervous system.
- polymorphism** A variation in DNA that is too common (occurs in greater than 1% of the population) to be due to a new mutation.
- polypharmacy** The concurrent use of multiple medications by a patient.
- polysomnogram** Procedure performed during sleep that involves monitoring the electroencephalogram (EEG), electrocardiogram (EKG), and respiratory efforts. It is used to investigate individuals with sleep disorders, including sleep apnea; *also called* a sleep study.
- polyuria** Excessive passage of urine.
- POR** See prevalence odds ratio.
- positive behavioral interventions and supports (PBIS)** Positive reinforcement used to control undesired behaviors.
- positive predictive value** The probability that individuals with a positive screening test truly have the disease.

- positive pressure ventilation** Application of positive pressure to the inspiratory phase when the patient has an artificial airway in place and is connected to a ventilator.
- positive punishment** Involves the contingent delivery of a consequence (*sometimes termed* an aversive stimulus).
- positive reinforcement** A method of increasing desired behaviors by rewarding them; exists when the contingent delivery of an outcome produces an increase in the likelihood of the behavior(s) upon which it is contingent.
- positive reinforcers** Any tangible (e.g., food or toy) or action (e.g., hug) that is reinforcing to an individual and will lead to a subsequent increase in the behavior that preceded it.
- positive support reflex (PSR)** Primitive reflex present in an infant, in which the child reflexively accepts weight on the feet when bounced, appearing to stand briefly.
- positron emission tomography (PET)** Imaging study utilizing radioactive-labeled chemical compounds to study the metabolism of an organ, most commonly the brain.
- postconceptional age (PCA)** Dates the onset of human development from the presumed date of ovulation (i.e., when fertilization occurs).
- posterior** In back of or the back part of a structure.
- postictal** Immediately following a seizure episode.
- postterm birth** Birth after 42 weeks' gestation.
- posttraumatic stress disorder (PTSD)** Psychiatric disorder in which a previously experienced stressful event is reexperienced psychologically many times and associated with anxiety and fear.
- postural reactions** Normal reflexlike protective responses of an infant to changes in position; *also called* automatic movement reactions.
- PPHN/PFC** See persistent pulmonary hypertension of the newborn/persistent fetal circulation.
- PPV** See positive pressure ventilation.
- pragmatics** The study of language as it is used in a social context (e.g., conversation).
- precocious puberty** A condition in which the changes associated with puberty begin at an unexpectedly early age.
- preeclampsia** Disorder of late pregnancy characterized by high blood pressure with swelling and/or protein in the mother's urine, seen especially in teenagers and women older than 35 years; *also called* toxemia of pregnancy; blood toxemia of pregnancy.
- preference assessments** Assessments to identify high-preference stimuli that may be potential reinforcers in a behavior management program.
- pregnancy-associated plasma protein A (PAPP-A)** A plasma protein that is used as a blood screening test between 8 and 14 weeks' gestation. Diminished levels of the protein suggest an increased risk for Down syndrome, intrauterine growth retardation, preeclampsia, and stillbirth.
- preimplantation genetic diagnosis (PGD)** Refers to procedures that are performed on embryos prior to implantation. PGD is considered another approach to prenatal diagnosis. When used to screen for a specific genetic disease, it avoids selective pregnancy termination as the method makes it highly likely that the baby will be free of the disease under consideration. PGD is an adjunct to assisted reproductive technology and requires *in vitro* fertilization (IVF) to obtain oocytes or embryos for evaluation.
- premolar** Teeth in the back of the mouth used for grinding.
- premutation** A sequence of multiply repeated nucleotides that may produce a disease in one's offspring but may not produce clinically apparent disease in the carrier. The classic example is fragile X syndrome, where CCG repeats of < 200 are considered premutations and repeats of > 200 are full mutations.
- prenatal screening** Noninvasive (usually maternal blood) tests used to screen for genetic disorders in the fetus.
- presbyopia** A decrease in the accommodation of the lens of the eye that occurs with aging.
- pretend play** Make-believe play.
- preterm birth** Birth prior to 37 weeks' gestation; prematurity.
- prevalence** The number of cases of a disease that are present in a particular population at a given time.
- prevalence odds ratio (POR)** The burden or status of a disease in a defined population at a specified time, including all cases of disease in the population whether they are newly diagnosed or previously recognized.
- priapism** Painful and long-lasting penile erections.
- primary neurulation** The process by which the neural plate develops a midline groove, the edges of which fold over, converge, and close to form the neural tube.
- primitive reflexes** Infantile reflexes that tend to fade in the first year of life (i.e., the suck, startle, and root) (*see* Chapter 21).
- promotor region** A segment of DNA usually occurring upstream from a gene coding region (exon) and acting as a controlling element in the expression of that gene.
- prompts** Cues (e.g., verbal and visual) that direct the child to participate in a targeted activity.
- prone** Face down.
- prophase** The initial stage in cell division when the chromosomes thicken and shorten to look like separate strands.
- prophylaxis** Use of a preventive agent.
- proprioception** Ability to sense the position, location, orientation, and movement of body parts.
- proptosis** Appearance of protruding eyes.
- prosencephalon** See forebrain. The forward-most bulge, gives rise to the left and right cerebral hemispheres.
- prosocial** Socially acceptable.
- prosody** The intonation and rhythm of speech.
- proteinuria** Protein in urine.
- proto-declarative pointing** Pointing in order to share interest or attention about an object. This developmental milestone typically appears between 9 and 14 months of age.

- proto-imperative pointing** Pointing in order to use another person to obtain an object. This developmental milestone typically appears between 12 and 14 months of age.
- proximal** Describing the part nearest the midline or trunk.
- proxy consent** Consent for treatment or research given by a parent or guardian for a child or an incompetent adult.
- pseudohypertrophy** Enlarged but weak muscle, as found in muscular dystrophy.
- pseudomonas** A bacterial infection that most commonly causes pneumonia in immunocompromised patients.
- PSR** *See* positive support reflex.
- psychoeducational** Pertaining to the testing of intelligence, academic achievement, and other types of psychological and educational processes.
- psychological assessment** Incorporates test scores into a broadly based assessment of a child's abilities and functioning; *also called* psychological testing.
- psychosis** A psychiatric disorder characterized by hallucinations, delusions, loss of contact with reality, and unclear thinking; *adjective*: psychotic.
- psychotherapy** Nonpharmacological treatment for an individual with an emotional disorder. Various types of psychotherapy range from supportive counseling to psychoanalysis with services usually provided by a psychologist, psychiatrist, or social worker.
- ptosis** Droopy eyelids.
- PTSD** *See* posttraumatic stress disorder.
- PUBS** *See* percutaneous umbilical blood sampling.
- pulmonary** Pertaining to the lungs.
- pulmonary hypertension** Increased back pressure in the pulmonary artery leading to decreased oxygenation and right heart failure.
- pulmonary vascular obstructive disease** This leads to increased back pressure in the arteries that connect the heart to the lungs and results in congestive heart failure.
- pulmonary vascular resistance (PVR)** Vasoconstriction of the pulmonary blood vessels normally high during fetal life, which should relax immediately upon birth with the first breaths of life.
- pulmonary vasodilation** Relaxation of the lung's blood vessels soon after birth to establish lung circulation and extinguish fetal circulation.
- pulp** The soft tissue under the dentin layer in teeth containing blood vessels, lymphatics (lymph vessels), connective tissue, and nerve fibers.
- pulse oximeter** A device that measures oxygen tension noninvasively.
- pulse oximetry screening** A newborn screening test that improves detection of critical congenital heart defects.
- punishment** In behavior management, a procedure or consequence that decreases the frequency of a behavior through the use of a negative stimulus or withdrawal of a preferred activity/object.
- pupil** The aperture in the center of the iris.
- purine** A type of organic molecule found in RNA and DNA.
- puritis** Itchiness.
- purpuric** Bruising indicating bleeding into the skin.
- purpuric skin lesions** Bruising.
- putamen** A part of the lentiform nucleus that is lateral to the globus pallidus in the brain. It is associated with the corpus striatum and receives connections from the suppressor centers of the cortex.
- PVL** *See* periventricular leukomalacia.
- PVR** *See* pulmonary vascular resistance.
- pyloric stenosis** A congenital narrowing of the opening from the stomach to the small bowel.
- pylorus** The sphincter at the junction of the stomach and the duodenum.
- pyramidal tract** A nerve tract; *also called* the corticospinal tract, leading from the cortex into the spinal column and involved in the control of voluntary motor movement. Damage to this tract results in spasticity, commonly seen in cerebral palsy.
- pyridoxine** Vitamin B₆.
- quadriplegia** Paralysis of all four extremities.
- quickenings** The first signs of life felt by the mother as a result of fetal movements in the fourth or fifth month of pregnancy.
- rad** A measure of radioactivity.
- radial-digital grasp** A grasp pattern emerging in the 8th–9th month of age characterized by holding an object between an opposed thumb and fingertips with the object held toward the distal end of these digits so that a space is visible between the thumb and the fingers.
- radial-palmar grasp** A baby will begin involving the thumb and all fingers, while using more of the thumb side of their hand to grab objects.
- radiograph** A medical x-ray.
- ratio schedules** Provision of reinforcement following a set number of correct responses.
- real-time ultrasonography** The use of sound waves to provide a moving (real-time) image used in fetal monitoring.
- rebound** A phenomenon in which as a medication dose wears off, a person's behavior or symptoms become worse than when completely off medication.
- receptive aphasia** Impairment of receptive language due to a disorder of the central nervous system (CNS).
- receptive language** The cognitive processing involved in comprehending oral, symbolic, or written language.
- recessive** Pertaining to a trait that is expressed only if the child inherits two copies of the gene; from the Latin word for "hidden."
- recti muscles** Eye muscles that converge the eyes toward the nose for near activities and diverge the eyes for far ones.
- recurrence risk** In medical genetics, the chance that an inherited disorder that is present in a family will recur in that family, affecting one or more other members in the future.

- red reflex** The reddish-orange reflection from the eye's retina that is observed when using an ophthalmoscope or retinoscope.
- refracted** Bent, toward a focal point.
- reframing** Reinterpreting a behavior by viewing it from a different lens and focusing on the adaptive and positive aspects rather than negative ones.
- regurgitation** The involuntary return of partially digested food from the stomach into the mouth.
- rehabilitation engineer** A specially trained engineer who designs, adapts, and evaluates technological solutions to problems confronting individuals with disabilities.
- reinforcer** A response to a behavior that increases the likelihood that the behavior will occur in the future.
- related services** Services (e.g., transportation, occupational and physical therapy) that supplement the special education services provided to a child with a developmental disability.
- renal dysplasia** Small, abnormal kidneys.
- repetitive microtrauma** Small injury of lesion that can become problematic if repetitive.
- representative payee** Often required by programs and services in order to disburse funds to an individual with developmental disabilities.
- resonance** In linguistics and speech-language pathology, the balance of air flow between the nose and the mouth.
- resonance disorders** Abnormal amounts of nasality, often caused by structural malformations, such as enlarged adenoids and tonsils, or structural anomalies, such as a deviated septum.
- respiratory technology assistance** Medical devices used to replace or augment a vital body function.
- response to intervention (RTI)** Represents a shift in thinking about students who have difficulty learning at the same rate as their peers. Students with learning difficulties are provided supplementary instruction within general education, with special education being the final rung on the ladder of support. RTI also concerns the diagnosis of students with specific learning disabilities (SLD). RTI was introduced by the Individuals with Disabilities Education Improvement Act (IDEA) of 2004 as an alternate and preferred method for diagnosing children with SLD. It is likely that when IDEA is next reauthorized, RTI will be the only acceptable method for diagnosing SLD.
- restrictive/repetitive behaviors and interests (RRBIs)** Core symptoms of autism spectrum disorder. They include repetitive movements with objects, repeated body movements such as rocking and hand-flapping, ritualistic behavior, sensory sensitivities, and circumscribed interests.
- retina** The photosensitive nerve layer that lines the back of the eye, senses light, and creates impulses that travel through the optic nerve to the brain.
- retinopathy** Disorder of the retina.
- retinopathy of prematurity (ROP)** A disorder involving abnormal blood vessel development in the retina of the eye in a premature infant. It has been linked to excessive provision of oxygen.
- retinoscope** An instrument used to detect errors of refraction in the eye.
- retro-illumination** In split-lamp examination of the eye, it is a method of illuminating a structure by using the light that is reflected by the iris or by a lens containing a cataract.
- retrospective payment system** Pertaining to a fee-for-service health care model in which payment occurs after services are rendered.
- retrovirus** The class of viruses that includes human immunodeficiency virus (HIV), the causative agent of acquired immunodeficiency syndrome (AIDS).
- Rh incompatibility** Condition occurring when an Rh+ baby is born to an Rh- mother. This leads to breakdown of red blood cells in the baby and the excessive release of bilirubin, predisposing the Rh+ baby to kernicterus.
- rhabdomyolysis** Breakdown of muscle tissue.
- rhombencephalon** The hindbrain region of the embryo.
- ribonucleic acid (RNA)** A nucleic acid that is an essential component of all cells, composed of a long, usually single-stranded chain of nucleotide units that contain the sugar ribose. It is essential for protein synthesis within the cell.
- ribosome** Intracellular structure involved in protein synthesis. It reads the genetic code delivered to it by mRNA.
- rickets** Bone disease resulting from nutritional deficiency of vitamin D.
- rights** Moral or legal claims by one party against another.
- rigid** Pertaining to increased tone marked by stiffness.
- ring chromosome** A ring-shaped chromosome formed when deletions occur at both tips of a normal chromosome with subsequent fusion of the tips, forming a ring.
- RNA** See ribonucleic acid.
- rods** Photoreceptor cells of the eye associated with low-light vision.
- rolandic epilepsy** An inherited benign form of epilepsy occurring in children and characterized by sudden episodes of arrested speech and muscular contractions of the side of the face.
- rootlets** Small branches of nerve roots.
- ROP** See retinopathy of prematurity.
- rostral** Anterior pole of the developing embryo.
- RTI** See response to intervention.
- rubella** A viral infection. Generally causes a mild elevation of temperature and skin rash and resolves in a few days. However, when it occurs in a pregnant woman during the first trimester, it can lead to intrauterine infection and severe birth defects; *also called* German measles.

Rubinstein-Taybi syndrome See Appendix B.

rumination The regurgitating and chewing again of previously swallowed food.

sacral Relating to the bone at the base of the spine.

SAH See subarachnoid hemorrhage.

salicylates Chemicals found in many food substances and in aspirin.

saline A salt solution.

Sally-Ann test A psychological test that measures a person's social cognitive ability to attribute false beliefs to others.

sarcomeres The contractile units of the muscle fiber.

Sarnat neurological score The most popular system for grading the severity of hypoxic ischemic encephalopathy (HIE); it ranges from 1 (mild) to 3 (severe) in neonates.

satiating Having had enough or too much of something.

scala media (SM) Fluid-filled cavity within the cochlea of the ear.

scala tympani (ST) One of the three spirally arranged canals into which the bony canal of the cochlea is partitioned.

scala vestibuli (SV) One of the three spirally arranged canals into which the bony canal of the cochlea is partitioned.

schizencephaly A severely malformed brain with clefts formed because of a neuronal migrational defect during early embryogenesis.

schizophrenia A psychiatric disorder with characteristic psychotic symptoms (i.e., prominent delusions, hallucinations, catatonic behavior, and/or flat affect).

Schlemm's canal The passageway in which the aqueous fluid leaves the eye.

Schwann cell A myelin-secreting glial cell that spirally wraps around an axon of the peripheral nervous system to form the myelin sheath.

sclera The thick, white nontransparent fibrous covering in the eye.

scoliosis Lateral curvature of the spine.

screening test A test designed to screen for, but not definitively diagnose, a particular condition.

SDH See subdural hemorrhage.

seborrheic dermatitis Dandruff.

secondary Occurring as a consequence of a primary disorder.

secondary neurulation A series of events at the lower edge of the neural tube in which the caudal eminence develops into the bottom most segments of the spine and elements of the lower intestine.

second-trimester ultrasonography An ultrasound conducted in the 13th–14th week of pregnancy to test for Down syndrome and other congenital anomalies.

secretin Hormone produced in the duodenum that stimulates secretion of pancreatic enzymes.

seizure threshold Tolerance level of the brain for electrical activity. If level of tolerance is exceeded, a seizure occurs.

selective serotonin reuptake inhibitors (SSRIs)

Commonly used medications for treatment of depression and anxiety. They act by decreasing reuptake of serotonin from the synaptic cleft, resulting in more serotonin being available for neurotransmission.

selective vulnerability Refers to a susceptibility of specific regions and cells to injury.

self-advocacy People with disabilities taking control of their own lives, including being in charge of their own care in the medical system.

self-injurious behavior (SIB) The intentional, direct injuring of body tissue most often done without suicidal intentions.

semantics The study of and conventions governing meanings of words.

semicircular canals The three bony fluid-filled loops in the bony labyrinth of the internal ear, associated with the sense of balance.

sensorineural Involving the cochlea or auditory nerve.

sensorineural hearing loss Hearing loss caused by damage to the sensory cells and/or nerve fibers of the inner ear.

sensory integration The ability to integrate the senses of touch (tactile), balance (vestibular), and where the body and its parts are in space (proprioceptive).

sensory integration (SI) therapy Therapy that uses controlled sensory stimulation combined with a meaningful adaptive response to achieve changes in learning and behavior. A common method used in occupational therapy.

sensory processing disorder (SPD) A condition in which the brain has trouble receiving and responding to information that comes in through the senses. It is not currently recognized as a distinct medical diagnosis.

separation anxiety Excessive concern about separation, usually of mother from child (e.g., school phobia).

sepsis Infection that has spread throughout the bloodstream and can be life threatening; *also called* blood poisoning.

sequential modification If desired changes in behavior are not observed to occur across settings and behaviors, concrete steps are taken to introduce the effective intervention (e.g., positive reinforcement) to each of the behaviors or settings to which transfer of effects is inadequate.

serotonin reuptake inhibitors A group of psychoactive drugs, an example being fluoxetine (Prozac) used to treat depression.

serum See plasma.

sex chromosomes The X and Y chromosomes that determine sex.

sex-linked trait See X-linked trait.

SGA See small for gestational age.

shadowing Technique in which the instructor keeps his or her hands within an inch of the child's hands as the child proceeds to complete the task.

shared decision making Patient or proxy and physician participate together in committing to a treatment decision.

SI therapy See sensory integration therapy.

sialorrhea A condition with marked drooling.

SIB See self-injurious behavior or aggressions.

SIDS See sudden infant death syndrome.

silent stroke A stroke without any outward symptoms.

single nucleotide polymorphisms (SNPs) DNA sequence variations in the population.

single photon emission computed tomography (SPECT)

An imaging technique that permits the study of the metabolism of a body organ, most commonly the brain.

single-gene defect A mutation or error in a single gene leads to disease. Examples include sickle cell disease and phenylketonuria.

SLD See spoken language disorder.

sleep apnea Brief periods of arrested breathing during sleep, most commonly found in premature infants and in older children and adults with morbid obesity.

sleep myoclonus Sudden jerking movements of the body associated with various sleep stages that may be confused with a seizure.

sleep onset latency The length of time it takes to transition from full wakefulness to sleep once one goes to bed.

small for gestational age (SGA) Refers to a newborn whose weight is below the 10th percentile for gestational age, often referencing prematurely born infants.

SNPs See single nucleotide polymorphisms.

social-emotional reciprocity The back-and-forth flow of social interaction.

social-negative reinforcement The removal of some unwanted or aversive event contingent on a behavior may also result in strengthening of that behavior and may take the form of escape or avoidance from the unwanted event.

social-positive reinforcement Events or stimuli that follow the occurrence of a behavior that may function to strengthen that behavior.

soft neurological signs A group of neurological findings that are normal in young children, but when found in older children suggest immaturities in central nervous system (CNS) development (i.e., difficulty performing sequential finger-thumb opposition, rapid alternating movements).

soft spot See anterior fontanelle.

somatic Relating to the body.

somatic nervous system (SNS) Part of the peripheral nervous system associated with the voluntary control of body movements via skeletal muscles and with sensory reception of touch, hearing, and sight.

somatosensory system The part of the sensory system concerned with the conscious perception of touch, pressure, pain, temperature, position, movement, and vibration that arise from the muscles, joints, and skin.

somatotopical Organization of the motor area of the brain so that specific regions of the cortex control movement of different areas of the body.

spastic Pertaining to increased muscle tone in which muscles are stiff and movements are difficult; caused by damage to the pyramidal tract in the brain and spinal cord.

spastic diplegia A form of cerebral palsy primarily seen in former premature infants that is manifested as spasticity of both lower extremities with only mild involvement of upper extremities.

spastic hemiplegia A form of cerebral palsy in which one side of the body demonstrates spasticity and the other side is unaffected.

spastic hypertonicity Increased muscle tone and a positive Babinski response, two of the hallmark features of spastic cerebral palsy.

spastic quadriplegia A form of cerebral palsy in which all four limbs are affected. Increased muscle tone (i.e., spasticity) is caused by damage to the pyramidal tract in the brain.

spasticity Abnormally increased muscle tone.

speaking valve A valve that can be used by children who have tracheostomy tubes to permit vocalizations.

specific language impairment A significant deficit in linguistic functioning that does not appear to be accompanied by deficits in hearing, intelligence, or motor functioning.

specific learning disability Includes disorders that affect the ability to understand or use spoken or written language; it may manifest in difficulties with listening, thinking, speaking, reading, writing, spelling, and/or doing mathematical calculations.

SPECT See single photon emission computed tomography.

spectrum of developmental disabilities The various neurological disorders that result from abnormalities in cognitive, motor, and neurobehavioral function.

speech and language disorders Problems in communication and related areas such as oral-motor function.

speech sound disorder (SSD) A communication disorder in which children have difficulty saying words or sounds correctly; an articulation disorder.

spoken language disorder (SLD) Also known as an oral language disorder, represents a significant impairment in the acquisition and use of language across modalities (e.g., speech, sign language, or both) due to deficits in comprehension and/or production across any of the five language domains (i.e., phonology, morphology, syntax, semantics, pragmatics).

splenomegaly Enlarged spleen.

spermatocytes Sperm.

spina bifida A developmental defect of the spine, a neural tube defect; *also called* spinal dysraphism.

spina bifida occulta Generally benign congenital defect of the spinal column not associated with protrusion of the spinal cord or meninges; the most common neural tube defect.

spinal braces A form of low-tech assistive device to children with cerebral palsy or neuromuscular disorder.

- spinal cord** The thick, whitish cord of nerve tissue that extends from the base of the brain down through the spinal column.
- spinal dysraphism** See spinal bifida.
- spinal muscular atrophy** Congenital neuromuscular disorder of childhood associated with progressive muscle weakness. See Appendix B.
- spinal tap** See lumbar puncture.
- spindle** In mitosis and meiosis, a weblike figure along which the chromosomes are distributed.
- spondyloepiphyseal dysplasia** Congenital structural abnormality of vertebral column caused by a lack of mineralization of bone. See Appendix B.
- spontaneous recovery** In behavior management, the recurrence of an undesirable behavior after it has been extinguished.
- sporadic** In genetics, describing a disease that occurs by chance and carries little risk of recurrence.
- SSRIs** See selective serotonin reuptake inhibitors.
- standardized rating scales** Questionnaires concerning specific behaviors that have been completed for large samples of children so that norms and normal degrees of variation are known.
- stapes** One of the three small bones in the middle ear, collectively called the ossicles, that help amplify sound.
- Staphylococcus aureus** The bacteria resulting in staph infections such as cellulitis.
- static encephalopathy** Characterized by significantly delayed development, with the acquisition of new skills at a slower rate than is typical.
- static** Unchanging.
- status epilepticus** A seizure lasting more than 30 minutes.
- stenosis** An abnormal narrowing.
- stereocilia** The sensory (hair) cells of the inner ear.
- stereotypic movement disorder** Disorder characterized by recurring purposeless but voluntary movements (e.g., hand flapping in children with autism); *also called* stereotypies.
- stereotypies** See stereotypic movement disorder.
- steroids** 1) Medications used to treat severe inflammatory diseases and infantile spasms; 2) certain natural hormones in the body.
- stimulant** Medication used to treat attention-deficit/hyperactivity disorder (e.g., methylphenidate).
- stomach flu** See gastroenteritis.
- strabismus** Deviation of one or both eyes during forward gaze; the loss of this coordinated movement leads to misalignment of the eye; crossed eyes.
- stranger anxiety** A developmental stage during which a child experiences anxiety when separated from the primary caregiver.
- subacute progressive encephalopathy** Characterized by a gradual and insidious loss of previously obtained cognitive and motor milestones.
- subarachnoid** Beneath the arachnoid membrane, or middle layer, of the meninges.
- subarachnoid hemorrhage (SAH)** Hemorrhage into the fluid-filled space between the arachnoid membrane and the underlying brain that can compress or contuse the underlying brain.
- subdural** Resting between the outer (dural) and middle (arachnoid) layers of the meninges.
- subdural hematoma** Localized collection of clotted blood lying in the space between the dural and arachnoid membranes that surround the brain. This results from bleeding of the cerebral blood vessels that rest between these two membranes.
- subdural hemorrhage (SDH)** Hemorrhage between the tough outer membrane (dura) and the meninges surrounding the brain and spinal cord that can compress or contuse the underlying brain.
- subluxation** Partial dislocation.
- submucosal** A supporting layer of loose connective tissue directly under a mucous membrane, (i.e., below the palate).
- subplate zone** A transient fetal area involved in the development of the cerebral cortex.
- substrate** A compound acted upon by an enzyme in a chemical reaction.
- sucrose** A sugar molecule composed of glucose and fructose.
- sudden infant death syndrome (SIDS)** Diagnosis given to a previously well infant (often a former premature baby) who is found lifeless in bed without apparent cause; *also called* crib death.
- sudden unexpected infant death (SUID)** Sudden death of an infant, with no obvious cause prior to investigation.
- sulci** Furrows of the brain; *singular*: sulcus.
- superior** In anatomy, above.
- supernumerary** Extra.
- supine** Lying on the back, face upward.
- supported employment** Defined by the Rehabilitation Act Amendments of 1986 (PL 99-506) and 1992 (PL 102-569) as employment in an inclusive setting with ongoing support services for an individual with a disability.
- suppository** Small solid medication shaped for ready introduction into one of the orifices of the body other than the oral cavity, such as the rectum, urethra, or vagina.
- surfactant** A lipoprotein normally secreted into the alveoli with the first breaths of life that acts like a soap bubble and allows for a significant decrease in the alveolar membrane's surface tension, thus making breathing much easier and the lungs much more flexible immediately after birth.
- surveillance** The ongoing monitoring of disease in the population.
- surveillance devices** Devices such as cardiorespiratory monitors and pulse oximeters.
- sutures** In anatomy, the fibrous joints between certain bones (e.g., skull bones).
- synapses** The minute spaces separating one neuron from another. Neurochemicals breach this gap.
- synaptic pruning** The process of elimination of excess axons and dendrites beginning at about 2 years of age and continuing throughout childhood and adolescence.
- syncopal episode** Fainting spell.

- syndactyly** Webbed hands or feet.
- synophrys** Confluent eyebrows.
- syntax** Word order.
- syphilis** A sexually transmitted disease that can cause an intrauterine infection in pregnant women and result in severe birth defects.
- syringomas** Benign sweat gland tumors.
- syringomyelia** A chronic disease of the spinal cord characterized by the presence of a fluid-filled cavity.
- syrinx** A pathological tube-shaped cavity in the spinal cord.
- systemic** Involving the body as a whole.
- T-cell lymphocyte population** White blood cells responsible for recognizing and chemically encoding into immunologic memory any foreign bacterial substances.
- tachycardia** Rapid heart rate.
- tachypnea** Rapid breathing.
- tactile** Relating to touch.
- talipes equinovarus** *See* clubfoot.
- tandem mass spectrometer (MS/MS)** A machine that separates and quantifies ions based on their mass-to-charge ratio. It is used in newborn screening to detect a number of inborn errors of metabolism.
- tangential migration** Cells migrate parallel to the surface of the brain and perpendicular to the radial glia.
- tangibles** Rewards given in positive reinforcement procedures (e.g., food or toys).
- tardive dyskinesia** A potentially severe movement disorder resulting from the long-term use of phenothiazines or other antipsychotic medication.
- target behaviors** Behaviors selected for assessment and management.
- tartar** *See* calculus.
- TCD** *See* transcranial Doppler.
- tectorial membrane** Attached to the cochlea of the inner ear.
- telangiectasia** Abnormal cluster of small blood vessels.
- telehealth** Electronic and video-based communication.
- telencephalon** The structure in the embryo that turns into the cerebral cortex, subcortical white matter, and basal ganglia.
- teletypewriter (TTY)** An electronic device for text communication via a telephone line used when one or more of the parties has hearing or speech difficulties.
- telophase** The final phase in cell division in which the daughter chromosomes are at the opposite poles of the cell and new nuclear membranes form.
- temporal lobe** Brain region involved in visual and auditory processing. The area of the cortex primarily involved in communication and sensation.
- tendons** Fibrous cords by which muscles are attached to bone or to one another.
- teratogens** Agents that can cause malformations in a developing embryo.
- testosterone** Male sex hormone.
- tethered** Tied down.
- tetraploid** Having four copies of each chromosome (i.e., 92 chromosomes). This is incompatible with life.
- thalamus** Region of the brain situated in the posterior part of the forebrain that relays sensory impulses to the cerebral cortex.
- theory of mind** The ability to intuit and understand others' thoughts, emotions, and perspectives, particularly when they differ from one's own experience.
- therapeutic drug monitoring** Management of a patient's medication based on measuring blood concentration of the drug over time.
- thickening agents** Can transform any thin liquid into a nectar-, honey-, or milkshake-like consistency.
- thimerosal** A mercury-containing organic compound that was in the past used as a preservative in vaccines.
- thoracolumbar kyphosis** Curvature of the mid-lower spine in the front to back plane.
- thrombocytopenia** Low platelet count.
- thrombophilia** A genetic tendency for one's blood to clot more than normal.
- thrush** Monilial (fungal) yeast infection of the oral cavity sometimes seen in infants.
- thymine** One of the four nucleotides (chemicals) that comprise DNA.
- thymus** A gland in the upper chest which plays a key role in regulating immune responses.
- thyrotoxicosis** A form of hyperthyroidism leading to severe symptoms.
- tics** Brief repetitive movements or vocalizations that occur in a stereotyped manner and do not appear to be under voluntary control.
- time-in** A behavioral procedure which dramatically increases pleasant social and physical contact between the child and caregiver.
- time-out** A procedure whereby the possibility of positive reinforcement is withdrawn for a brief amount of time following the occurrence of a targeted challenging behavior.
- TLR** *See* tonic labyrinthine reflex.
- tocolysis** Use of medications to stop preterm labor.
- Todd's paralysis** Reversible weakness of one side of the body following a seizure.
- tonic** Effect of prolonged muscular contraction on tone.
- tonic labyrinthine response** A primitive reflex found in newborns. Tilting the head back while lying on the back causes the back to stiffen and arch backwards; the legs to straighten, stiffen, and push together; the toes to point; the arms to bend at the elbows and wrists; and the hands to become fistled or the fingers to curl. *Also called* tonic labyrinthine reflex (TLR).
- tonic-clonic** Spasmodic alteration of muscle contraction and relaxation.
- tonotopic organization** Pertaining to the spatial arrangement of where sound is perceived, transmitted, or received.
- tonotopic tuning** Process occurring between 28 and 30 weeks' gestation by which exposure to sounds in the intrauterine environment allows the cochlea to begin fine-tuning its response to different frequencies of sound.

- tonotopically** Arranged spatially by tone as found in the cochlea of the inner ear.
- tooth bud** See dental organ.
- TORCH** See Appendix B.
- torticollis** Wry neck in which the neck is painfully tilted to one side; a form of dystonia.
- toxemia** See preeclampsia.
- toxoplasmosis** An infectious disease caused by a microorganism, which may be asymptomatic in adults but can lead to severe fetal malformations.
- Toxoplasmosis gondii** A parasite that can cause an intrauterine infection and birth defects.
- trachea** Windpipe.
- tracheal intubation** Introducing a tube into the airway to facilitate breathing.
- tracheoesophageal fistula** A congenital connection between the trachea and esophagus leading to aspiration of food and requiring surgical correction.
- tracheomalacia** Softening of the cartilage of the trachea.
- tracheostomy** The surgical creation of an opening into the trachea to permit insertion of a tube to facilitate mechanical ventilation.
- tracheostomy tube** A catheter that is inserted into the trachea for the purpose of supplying air.
- trachoma** A bacterial infection causing blindness in developing countries.
- transcranial Doppler (TCD)** An instrument that emits ultrasonic beams to diagnose vascular disease in the head.
- transcription** The process in which mRNA is formed from a DNA template.
- transition individualized education program (transition IEP)** A written plan for an adolescent receiving special education services that maps out his or her postschool education, services, and employment and adult living goals. It is required by federal law (IDEA, 2004) to be part of the student's IEP starting at age 16; *previously called* individualized transition plan (ITP).
- transitional (fetal) circulation** Circulatory changes occurring at birth in the lungs and around the heart, resulting from pulmonary vasodilation and closure of the ductus arteriosus and the foramen ovale (the two fetal bypasses around the lungs during fetal life).
- translation** A process where the mRNA moves out of the nucleus into the cytoplasm, where it provides instructions for the production of a protein.
- translocation** The transfer of a fragment of one chromosome to another chromosome.
- transplacental transmission** The passage of microbes from the maternal to fetal circulation via the placenta.
- tremor** A trembling motion.
- Treponema pallium** Microorganism causing syphilis.
- trichotillomania** Recurrent pulling out of one's hair.
- triplet repeat expansion** Abnormal number of copies of identical triplet nucleotides (as occurs in fragile X syndrome; see Chapter 15).
- triploid** Having three copies of each chromosome (i.e., 69 chromosomes), which is generally incompatible with life.
- trisomy** A condition in which there are three copies of one chromosome rather than two (e.g., trisomy 21, Down syndrome).
- trochlear nerve** The fourth cranial nerve controls the superior oblique eye muscle.
- trophoblast** The outermost layer of cells that attaches the fertilized egg to the uterine wall.
- TTY** See teletypewriter.
- tubers** Benign growths found in the brain of an individual with tuberous sclerosis.
- twinning** The production of twins.
- tympanic membrane (TM)** Eardrum.
- tympanometry** The measurement of flexibility of the tympanic membrane as an indicator of a middle-ear infection or fluid in the middle ear.
- tympanostomy** A small tube inserted through the tympanic membrane after myringotomy to aerate the middle ear; often used in the treatment of recurrent or persistent otitis media (middle ear infection).
- tyrosine** An amino acid.
- UES** See upper esophageal sphincter.
- umbilical cord prolapse** The umbilical cord being born before rather than after the baby, thereby becoming compressed by the fetus during the delivery process and interfering with oxygen flow to the fetus during labor.
- undernutrition** Inadequate nutrition to sustain normal growth.
- uniparental disomy** See genomic imprinting.
- unsaturated fatty acid** A type of dietary fat, certain kinds of which have been linked to heart disease.
- upper esophageal sphincter (UES)** A muscle at the entrance to the esophagus.
- urea** End product of protein metabolism.
- urea cycle disorders** A group of inborn errors of metabolism. See Appendix B.
- uremia** The abnormal accumulation of urinary waste products in the blood present in renal (kidney) failure.
- ureterostomy** Surgical procedure creating an outlet for the ureters through the abdominal wall.
- urethra** Canal through which urine passes from the bladder.
- urodynamics** A test that accesses how the bladder and urethra are performing their job of storing and releasing urine.
- urticarial** Hives.
- valgus** Condition in which the distal body part is angled away from the midline.
- varicella** The virus that causes chickenpox and shingles.
- varus** Condition in which the distal body part is angled toward the midline.
- vascular occlusion** Blockage of a blood vessel.
- vasoconstriction** A decrease in the diameter of blood vessels.
- vasodilation** Relaxation and dilation of blood vessels.
- vaso-occlusive episode** In sickle cell disease, the sudden restriction of blood flow due to sickle-shaped red blood cells blocking capillaries.

- ventilator** A machine that provides a mixture of air and oxygen to an individual in respiratory failure.
- ventral** Front.
- ventral induction** Describes development of the prosencephalon, its division into two sections, the telencephalon and diencephalon, and cleavage of the telencephalon into two cerebral hemispheres.
- ventricles** Fluid-filled cavities, especially in the heart or brain.
- ventricular septal defect** A congenital heart defect in which the wall separating the two lower chambers of the heart does not close during embryonic development.
- ventricular system** Interconnecting cavities of the brain containing cerebrospinal fluid.
- ventriculomegaly** Enlargement of the cerebral ventricles, usually seen in hydrocephalus.
- ventriculoperitoneal shunt (VP shunt)** Surgically placed tube connecting a cerebral ventricle with the abdominal cavity; used to treat hydrocephalus by draining cerebrospinal fluid into the child's abdominal cavity.
- ventriculo-subgaleal shunt** Implanted as a temporary measure for treatment of hydrocephalus, draining cerebrospinal fluid from the ventricles to the scalp.
- vertebral arches** The bony arches projecting from the body of the vertebra.
- vertex presentation** Downward position of infant's head during vaginal delivery.
- vertical transmission** Mother-to-child transmission of infection, especially in human immunodeficiency virus (HIV).
- very low birth weight (VLBW)** Term often used to describe an infant with a birth weight less than 1,500 grams (3 1/3 pounds).
- vesicles** Small bladderlike cavities containing specific chemicals (e.g., neurotransmitters).
- vesicostomy** The surgical creation of an opening for the bladder to empty its contents through the abdominal wall.
- vestibular apparatus (VA)** *See* vestibular system.
- vestibular system** Three ring-shaped bodies located in the labyrinth of the ear that are involved in maintenance of balance and sensation of the body's movement through space.
- villi** Vascular projections, such as those coming from the embryo that become part of the placenta; *singular: villus*.
- visceral** Relating to the soft internal organs of the body, especially those contained within the abdominal and thoracic cavities.
- vision impairment** A condition characterized by a loss of visual acuity, where the eye does not see objects as clearly as usual, or a loss of visual field, where the eye cannot see as wide an area as usual without moving the eyes or turning the head.
- visual acuity** The clarity of vision.
- vitiligo** A skin disease marked by patches of lack of pigment.
- vitreous humor** The gelatinous content of the eye located between the lens and retina.
- VLBW** *See* very low birth weight.
- volunteering** An opportunity for adolescents to gain valuable insight into the world of work, to develop skills, and to build work-related experience.
- VP shunt** *See* ventriculoperitoneal shunt.
- watershed area** Area of tissue lying between two major arteries and thus poorly supplied by blood.
- watershed infarct** Injury to brain due to lack of blood flow in the brain tissues between interfacing blood vessels.
- whole-exome sequencing (WES)** A genomic technique for sequencing all of the protein-coding genes in a genome (known as the exome).
- work-study employment** Part-time work for students sanctioned by the school either on or off campus.
- xerosis** Dryness of eyes.
- xerostomia** Dry mouth.
- X-linked trait** A trait transmitted by a gene located on the X chromosome; *previously called* sex-linked.
- Zika virus** A virus that can cause an intrauterine infection and severe microcephaly in an affected baby.
- zone of proximal development** The distance between the actual developmental level as determined by independent problem solving and the level of potential development under guidance.
- zygote** Fertilized egg.

APPENDIX **B**

Syndromes and Inborn Errors of Metabolism

Kara L. Simpson

The underlying cause of a developmental disability can be explained in some children by a single genetic or teratogenic mechanism. An understanding of the etiology can shed light on the reason for clinical features such as physical malformations, cognitive impairments, and behavior problems. Making a diagnosis in such cases may be important for physicians to implement appropriate medical management or to provide genetic or prenatal counseling. Other professionals may also find that a diagnosis assists them in the development of more global aspects of the child's care, including educational, physical, occupational, and speech-language therapy. The direct benefit to families includes the ability to gather information specific to their child's condition and to seek out support from other parents and/or affected individuals through support groups, conferences, and the Internet. Finally, attaining a specific diagnosis can lead patients, families, and health care professionals to the appropriate disease-oriented organization, which is often a great source of information and support (not just medical, but also emotional and sometimes financial as well). For all of these reasons, the search for an etiology of a child's developmental disability may focus on syndrome identification.

By definition, a *syndrome* is a recurring, recognizable pattern of structural defects and/or secondary effects that represents a single etiology. Syndromes may have a genetic basis (such as chromosomal or single-gene defects; see Chapter 1), can be environmental (e.g., teratogens; see Chapter 2), or can be complex (caused by more than one genetic and/or environmental factor). Genetic syndromes affect multiple organ systems because the genetic defect is usually contained in every cell of the body. This abnormality may interfere with

typical development or cause abnormal differentiation of more than one tissue of the body. Many genetic and teratogenic syndromes are of prenatal onset and are evident at birth, usually because of an unusual appearance (i.e., dysmorphic features) or multiple congenital abnormalities. Syndromes are usually stable conditions, and neurological regression is uncommon. A *sequence* is a situation where a single event leads to a single anomaly that has a cascading effect of local and/or distant deformations and/or disruptions. An *association* is a nonrandom occurrence of anomalies with no consistent etiology.

Unlike most syndromes, *inborn errors of metabolism* are usually not evident at birth. During pregnancy, the mother's normal metabolism usually protects the fetus. After delivery, however, there may be an accumulation of toxic metabolites as a result of an enzyme deficiency. The presentation of inborn errors varies from metabolic crisis and death within days of birth to occasional episodes in response to external factors later in childhood. Some metabolic disorders are treatable, and many in this category of genetic conditions are detectable with newborn screening through biochemical or molecular testing (see Chapters 4 and 17). Others, despite early diagnosis and treatment, still lead to irreversible effects.

Although the clinical features associated with certain syndromes and inborn errors of metabolism have been known for centuries (e.g., Down syndrome and congenital hypothyroidism), the chromosomal and molecular basis of the disorders has only been characterized since the 1960s. An increasing number of genetic and biochemical tests can now be utilized to confirm a clinically suspected diagnosis. This is of particular importance because different therapeutic

options (or the opportunity to participate in clinical research trials) may be available to individuals on the basis of a genetic diagnosis, particularly in the cases of molecularly based therapies. In addition, a genetic diagnosis allows for accurate recurrence risk estimates, the possibility of invasive prenatal testing on a subsequent pregnancy, and appropriate genetic counseling for other family members.

Diagnostic testing in patients with developmental delay, intellectual disability, congenital anomalies, and dysmorphic features has evolved significantly in the last several years, with the addition of cytogenetic microarrays based on comparative genomic hybridization (CGH) and single nucleotide polymorphism array analyses, as well as next-generation sequencing (NGS) panels and whole-exome sequencing (WES).

With the array CGH, copy number variants are determined by comparing the hybridization pattern intensities between an individual's DNA and control DNA. Microarrays are considered the first-tier clinical test for those with developmental disabilities, congenital anomalies, and autism spectrum disorder. NGS refers to non-Sanger-based, high-throughput DNA sequencing, which allows for billions of DNA strands to be sequenced in parallel. This allows large panels of genes to be tested simultaneously, which is very useful for syndromes with large numbers of associated genes. WES allows for sequencing of the entire exome, which has been helpful in determining new phenotypes of known syndromes and outlining new syndromes. However, the significance of many of the changes found on WES are not yet known, in addition to the possibility of incidental findings and their impact on a family.

It should be noted that genetic testing is frequently not straightforward and often contains changes of unknown significance. It is recommended that the ordering of any genetic testing be done by genetics teams as they have the appropriate resources to explain the results and consequences to patients (see Wallace, S. E., & Bean, L. J. H. [2017]. Educational materials—genetic testing: Current approaches. In M. P. Adam, H. H. Ardinger, R. A. Pagon, S. E. Wallace, L. J. H. Bean, K. Stephens, & A. Amemiya. [Eds.]. *GeneReviews*. Seattle, WA: University of Washington. Retrieved from <https://www.ncbi.nlm.nih.gov/books/NBK279899/>).

Research on the cognitive abilities of individuals with genetic syndromes has uncovered specific learning and behavior patterns for many syndromes. These are called behavioral phenotypes, and they can be used to establish rational and attainable educational goals to promote a child reaching his or her full cognitive and functional potential (Battaglia, A. & G. S. Fisch. [2010]. Behavioral phenotypes in neurogenetic

syndromes. *American Journal of Medical Genetics Part C: Seminars in Medical Genetics*, 154C[4], 387–485). Insight into an individual's specific condition, the behavioral phenotype, cognitive abilities, and learning strengths and weaknesses can be of particular importance in the classroom. References addressing the cognitive and behavioral abilities of individuals with specific genetic conditions are included in this appendix when possible. Some syndromes, however, are so rare that there are not enough data to outline a behavioral phenotype.

Many excellent resources concerning genetic conditions exist for families and health care professionals caring for children with disabilities. Some useful ones include the following:

- **The Genetic Alliance** is a nonprofit organization with a directory of support groups, foundations, research organizations, patient advocacy groups, and tissue registries. The Genetic Alliance is based in Washington, D.C. (202-966-5557; <http://www.geneticalliance.org>; e-mail: info@geneticalliance.org).
- **The Genetic and Rare Diseases Information Center** (GARD; 888-205-2311; <https://rarediseases.info.nih.gov/diseases>) is a program of the National Center for Advancing Translational Sciences (NCATS) and is funded by two parts of the National Institutes of Health (NIH): NCATS and the National Human Genome Research Institute (NHGRI). GARD provides the public with access to current, reliable, and easy-to-understand information about rare or genetic diseases in English or Spanish.
- **GeneReviews** (<https://www.ncbi.nlm.nih.gov/books/NBK1116/>) is administered by the University of Washington and funded by the National Institutes of Health (NIH), the Health Resources and Services Administration (HRSA), and the U.S. Department of Energy (DOE). GeneReviews provides peer-reviewed articles on genetic conditions that include information on diagnosis, management, and genetic counseling of individuals with specific inherited disorders and their families. It also provides relevant resources specific to each disease.
- **The National Organization for Rare Disorders** (NORD; 203-744-0100, toll-free 800-999-6673; <http://www.rarediseases.org>) is a nonprofit patient advocacy organization dedicated to orphan diseases (disorders occurring in less than 200,000 individuals in the United States). NORD provides information about diseases, referrals to patient organizations, research grants and fellowships, advocacy for the rare-disease community, and medication assistance programs.

- **The Online Mendelian Inheritance in Man** (OMIM; <http://www.ncbi.nlm.nih.gov/omim>) catalog describes all known Mendelian disorders and over 12,000 genes, providing clinical, biochemical, genetic, and therapeutic information. OMIM is authored and edited at the McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine.
- **The Genetics Home Reference**, sponsored by the U.S. National Library of Medicine (<http://ghr.nlm.nih.gov/>), is an excellent resource for health care professionals, teachers, and families, providing basic information about genetics and searchable disease-specific data.

HOW ENTRIES ARE ORGANIZED

This appendix lists a number of syndromes and inborn errors of metabolism that are often associated with developmental disabilities. Included in each listing are the disease category, principal characteristics, pattern of inheritance, frequency of occurrence (prevalence or incidence), treatment options when available, and recent references that further define the syndrome. Cognitive and behavioral changes are noted for disorders in which common developmental abnormalities are widely accepted as being part of the syndrome or inborn error. When known, the causative gene or chromosome location is listed. In describing the chromosomal location, the first number or letter indicates the chromosome on which there is a genetic change (mutation), and the subsequent letter (*p* or *q*) indicates the short or long arm of the chromosome, respectively. The term *ter* is used when the site is at the terminal end of one arm of the chromosome, and *cen* is used when the site is near the **centromere**. The numbers following the *p* or *q* specify the location on the chromosome. For example, Aarskog-Scott syndrome is located on the short arm of the X chromosome at position 11.21, designated as Xp11.21. The inheritance patterns of genetic traits are listed as autosomal recessive (AR), autosomal dominant (AD), X-linked recessive (XLR), X-linked dominant (XLD), mitochondrial (M), new mutation (NM; i.e., diseases caused by new mutations that arise in the sperm or the egg), or sporadic (SP; i.e., noninherited). Each syndrome has been assigned to a disease category, which is defined next. Although this appendix lists a number of the more commonly recognized syndromes associated with developmental disabilities, it is not intended to be all-inclusive. Specific medical terminology is defined in the Glossary (see Appendix A).

DISEASE CATEGORIES

auditory disorders Diseases that affect hearing.

chromosome abnormality Disorder due to a duplication, loss, or rearrangement of chromosomal material.

chromosome breakage syndromes Syndromes associated with increased rates of chromosomal breakage or instability due to defects in DNA repair mechanisms or genomic instability that leads to chromosomal rearrangements.

connective tissue disorders Disorders that affect the connective tissue, the tissue that helps support, binds together, and protects organs.

contiguous gene defect A disorder due to deletion of multiple genes that are adjacent to one another.

endocrine disorder Disorder affecting the endocrine systems glands and secretions (hormones).

immunodeficiency Disorder affecting the immune system which results in a weakened ability to fight off infections.

inborn errors of metabolism Genetic disorders that disrupt metabolism. Most are due to defects of single genes that code for enzymes that break down substrates. Each inborn error of metabolism has been categorized based on the main type of metabolism affected (e.g., carbohydrate, amino acid, organic acid, lysosomal storage disease, or copper).

imprinting defect Group of disorders where there is a defect in the process of genomic imprinting (where certain alleles are expressed based on the parent of origin).

malformation Birth defect that results from intrinsic defects in genes that control development.

multiple congenital anomalies Structural defects that are present at birth and affect multiple structures and organs.

neurological disorders Disorders mainly affecting the brain, spinal cord, and nerves.

neuromuscular diseases Diseases that affect the muscles and/or the nerves that control them.

ophthalmologic disorders Diseases that affect the eye.

overgrowth syndromes Disorders in which there is an abnormal increase in the size of the body or of a specific body part.

peroxisomal disorders A group of disorders caused by a deficiency in enzymes within the peroxisome (an organelle involved in metabolism of very long-chain fatty acids, biosynthesis of plasmalogens, and energy metabolism), or proteins encoded by genes for normal peroxisome assembly.

skeletal dysplasia A group of disorders characterized by abnormalities of bone and cartilage.

SYNDROMES AND DISORDERS

Aarskog-Scott syndrome (faciodigitogenital syndrome or faciogenital dysplasia) *Disease category:* Multiple congenital anomalies. *Clinical features:* Short stature, brachydactyly (short fingers and toes), widow's peak, broad nasal bridge with small nose, hypertelorism, shawl scrotum, and cryptorchidism (undescended testes); learning disabilities and behavioral problems are present in a subset of patients. *Associated complications:* Ptosis, eye movement problems, strabismus, orthodontic problems, and occasional cleft lip/palate. *Cause:* Mutations in *FGD1* (Xp11.21). *Inheritance:* XLR, with partial expression in some females. *Prevalence:* 1:25,000.

Verhoeven, W. M. A. (2012). X-linked Aarskog syndrome: Report on a novel *FGD1* gene mutation. Executive dysfunction as part of the behavioural phenotype. *Genetic Counseling*, 23(2), 157.

achondroplasia *Disease category:* Skeletal dysplasia. *Clinical features:* The most common form of short stature, associated with rhizomelic (proximal) shortening of the arms and legs, a large head with typical facial features (including frontal bossing and midface hypoplasia), genu varum (bow legs), and trident appearance of the hands. Hypotonia and motor delay is common. Cognitive development and life span are usually normal, although cervical spinal cord compression and upper airway obstruction increase risk of death in infancy. Newer studies show there may be some impairment of verbal IQ, attention, and executive function. Children with achondroplasia should be monitored for changes in their neurological status, particularly if there are concerns about delayed motor development. *Prevalence:* 1:26,000–1:28,000. *Cause:* 98% of affected individuals have a common point mutation in *FGFR3* (4p16.3). *Inheritance:* AD; 80% of cases are caused by NM.

acrocephalosyndactyly, type I *See* Apert syndrome.

acrocephalosyndactyly, type II *See* Carpenter syndrome.

acrocephalosyndactyly, type V *See* Pfeiffer syndrome.

acrofacial dysostosis (Nager syndrome) *Disease category:* Multiple congenital anomalies. *Clinical features:* Downslanting palpebral fissures, micrognathia (small jaw), midface retrusion (backward movement of the mandible), downward slant of eyelids, high nasal bridge, external ear defects, occasional cleft lip/palate, and asymmetric limb anomalies (hypoplastic thumb or radius [a bone in the lower arm]). *Associated complications:* Scoliosis, severe conductive hearing loss, occasional heart or kidney defects, and typically normal intelligence. *Cause:* Mutations in *SF3B4* (1q21.2). *Inheritance:* AD. *Prevalence:* Rare.

References: Bernier, F. P., Caluseriu, O., Ng, S., Schwartzentruber, J., Buckingham, K. J., Innes, A. M., . . . Parboosing, J. S. (2012). Haploinsufficiency of *SF3B4*, a component of the pre-mRNA spliceosomal complex, causes Nager Syndrome. *American Journal of Human Genetics*, 90, 925–933.

Czeschik, J. C., Voigt, C., Alanay, Y., Albrecht, B., Avci, S., Fitzpatrick, D., . . . Wieczorek, D. (2013). Clinical and mutation data in 12 patients with the clinical diagnosis of Nager syndrome. *Human Genetics*, 132, 885–898.

adrenoleukodystrophy (X-linked ALD) *Disease category:* Neuromuscular disease (for neonatal form, *see* adrenoleukodystrophy, neonatal form). *Clinical features:* Progressive neurological disorder of white matter resulting from accumulation of very long-chain fatty acids; three main phenotypes are seen in affected males. Those with the childhood cerebral form develop normally until between the ages of 4–8 years. Symptoms initially resemble attention-deficit disorder or hyperactivity. Impairment of cognition, behavior, vision, hearing, and motor function develop following initial symptoms

and lead to total disability within 2 years. A second phenotype called adrenomyeloneuropathy (AMN) manifests most commonly in the late twenties, as progressive paraparesis (paralysis), sphincter disturbances, sexual dysfunction, and often impaired adrenocortical function. The third phenotype is known as “Addison disease only” and presents with primary adrenocortical insufficiency between age 2 and adulthood without evidence of neurologic abnormality (but can develop later). *Associated complications:* Progressive intellectual deterioration, seizures, endocrine abnormalities, and conductive hearing loss. *Cause:* Mutations in *ABCD1* (Xq28). The ALD protein product is localized to the peroxisomal membrane. *Inheritance:* XLR, with intrafamilial variability ranging from classical childhood-onset ALD to adult-onset ALD to Addison disease; 93% of affected individuals inherit the *ABCD1* mutation from one parent, and 7% from NM. Approximately 20% of females who are carriers develop neurologic manifestations that resemble AMN but have later onset and milder disease than affected males. *Prevalence:* 1:20,000–1:50,000. *Treatment:* Corticosteroid replacement therapy for adrenal insufficiency (will not alter neurologic symptoms). Bone marrow transplant can provide long-term stability and may reverse some neurologic complications in the early stages. Dietary modifications including “Lorenzo’s oil” (oleic acid and erucic acid) have been shown to lower VLCFA levels, but clinical effects are still under investigation.

Aicardi syndrome *Disease category:* Neurologic. *Clinical features:* Infantile spasms, agenesis (absence) of the corpus callosum, and abnormalities of eyes (specifically chorioretinal lacunae). *Associated complications:* Poorly controlled seizures, visual impairment, cortical malformations, vertebral and rib abnormalities,

vascular malformations or malignancy, microphthalmia, hypotonia, microcephaly, and moderate to severe intellectual disability. Survival varies, but mean age of death is about 8.3 years, and median age of death is about 18.5 years. *Cause:* No gene or candidate region on the X chromosome has been definitively identified. *Inheritance:* XLD/NM; previously it has been assumed that mutations are lethal in males as Aicardi syndrome has been seen almost exclusively in females or 47, XXY Klinefelter males. More recently there have been rare reports of 46, XY male patients. *Prevalence:* 1:105,000–1:167,000 in the United States.

References: Kroner, B. L., Preiss, L. R., Ardini, M. A., & Gailard, W. D. (2008). New incidence, prevalence, and survival of Aicardi syndrome from 408 cases. *Journal of Child Neurology*, 23, 531–535.

Aicardi-Goutières syndrome (AGS) *Disease category:* Neurologic. *Clinical features:* Early-onset encephalopathy whose clinical features mimic those of acquired *in utero* viral infection. Normal pregnancy, delivery, and neonatal period in 80% of those affected; 20% present with brain calcifications *in utero* and present at birth with abnormal neurologic findings, hepatosplenomegaly, elevated liver enzymes, and thrombocytopenia. The rest of affected infants present at variable times, usually after a period of normal development. They present with subacute onset of severe encephalopathy characterized by extreme irritability, intermittent sterile pyrexias (fevers), loss of skills, and slowing of head growth. *Associated complications:* Peripheral spasticity, dystonic posturing of upper limbs, truncal hypotonia, poor head control, and seizures. Almost all affected individuals have severe intellectual and physical impairment. *Cause:* Seven causative genes have been found: *TREX1* (3p21.3-p21.2), *RNASEH2B* (13q14.1), *RNASEH2C* (11q13.2), *RNASEH2A* (19p13.13), *ADAR* (1q21.3), and *SAMHD1* (20q11.23). *Inheritance:* The majority of cases are AR, although there are AD/NM mutations in *TREX1*. *Prevalence:* Unknown.

alcohol-related neurodevelopmental defects (ARND)

Previously called fetal alcohol effects (FAE); see Chapter 2.

Alexander disease *Disease category:* Neurologic. *Clinical features:* Progressive cortical white matter neurological disorder that mostly affects infants and children and results in early death. General characteristics of the disease include seizures, intellectual disability, white matter abnormalities, and megalencephaly (enlarged head). The neonatal form usually ends in death within 2 years. The infantile form presents by age 2, and affected children survive up to several years. The juvenile form presents between ages 4–10 (and occasionally in the teens), and affected individuals survive until early teens to mid-20s and 30s. An adult form has been described, although with variable presentation. *Associated complications:* Hydrocephalus, demyelination, progressive spasticity, and visual impairment; bulbar signs are present in some patients. *Cause:* Mutations in *GFAP* (17q21). *Inheritance:* Majority of cases are caused by an NM with AD inheritance when passed from an affected individual; rare AD families have been reported. *Prevalence:* Rare.

References: Graff-Radford, J., Schwartz, K., Gavrilova, R. H., Lachance, D. H., & Kumar, N. (2014). Neuroimaging and clinical features in type II (late-onset) Alexander disease. *Neurology*, 82, 49–56.

Angelman syndrome *Disease category:* Imprinting defect/multiple congenital defect/contiguous gene defect. *Clinical features:* Severe developmental delay or intellectual disability, severe speech impairment, gait ataxia, and unique behavior with an inappropriate happy demeanor that includes frequent laughing, smiling, and excitability. *Associated complications:* Seizures and microcephaly. Behavioral features include hyperactivity, short attention span, hand flapping, feeding problems, chewing/mouthing behaviors, fascination with water, and abnormal food-related behaviors. *Cause:* Deletion of 15q11–q13 on the maternally inherited chromosome, paternal inheritance of both copies of chromosome 15 (uniparental disomy, or UPD), a point mutation in the maternal copy of *UBE3A* or an imprinting defect (due to deletion or epigenetic effect). *Inheritance:* All three causes arise as a result of NM; mutations in the *UBE3A* gene may be passed in an AD fashion. *Prevalence:* 1:10,000–1:20,000.

Apert syndrome (acrocephalosyndactyly, type I)

Disease category: Craniosynostosis. *Clinical features:* Craniosynostosis (premature fusion of the cranial sutures) with misshapen head (turribrachycephalic skull shape), high forehead, and flat occiput (back part of head); hypertelorism with downward slant; moderate-to-severe midface hypoplasia (flat midface) and nasal bridge; severe syndactyly (webbing of fingers or toes); limb anomalies; and cleft palate, hypertelorism, and fused cervical vertebrae. *Associated complications:* Hydrocephalus, varying degrees of intellectual disability, hearing loss, teeth abnormalities, and occasional heart and kidney anomalies. *Cause:* Mutations in *FGFR3* (10q26). *Inheritance:* Majority of cases are caused by an NM, with AD inheritance when passed from an affected individual. *Incidence:* 1:100,000. *Treatment:* Early neurosurgical correction of fused sutures improves appearance and may reduce risk of intellectual disability; plastic/orthopedic surgery for limb anomalies.

ARND Alcohol-related neurodevelopmental disorder; see Chapter 2.

arthrogryposis multiplex congenita

Disease category: Neuromuscular disease. *Clinical features:* Nonprogressive joint contractures that begin prenatally; flexion contractures at the fingers, knees, and elbows, with muscle weakness around involved joints. *Associated complications:* Occasional kidney and eye anomalies, cleft palate, defects of abdominal wall, and scoliosis. *Cause:* Multiple; most frequently related to an underlying neuropathy, myopathy (muscle weakness), or *in utero* crowding; may be associated with maternal myasthenia gravis. Nerve conduction studies/electromyography (EMG) and muscle biopsy

may be beneficial in determining the basis of the condition (myopathic versus neurogenic). Intelligence is usually normal. *Inheritance*: Usually SP and may be caused by teratogenic exposure; however, both AD and AR inheritance also have been reported. *Incidence*: 1:3,000–1:12,000. *Treatment*: Casting of affected joints or surgery, if indicated.

References: Ma, L., & Yu, X. (2017). Arthrogryposis multiplex congenita: Classification, diagnosis, perioperative care, and anesthesia. *Frontiers of Medicine*, 11(1), 48–53.
Skaria, P., Dhal, A., & Ahmed, A. (2017). Arthrogryposis multiplex congenital in utero: radiologic and pathologic findings. *Journal of Maternal-Fetal & Neonatal Medicine*, 27, 1–10.

ataxia telangiectasia *Disease category*: Chromosome breakage syndrome. *Clinical features*: Slowly progressive ataxia, telangiectasias (dilation of capillaries, especially in the sclera [whites of eye] and behind the earlobe), small cerebellum. immune defects, and elevated alpha-fetoprotein in blood. *Associated complications*: Dystonia or choreoathetosis, dysarthric speech (imperfect articulation due to decreased motor control), increased sensitivity to radiation, increased risk of malignancy (especially leukemia or lymphoma), eye movement abnormalities, finger contractures, and increased risk of sinus and pulmonary infections; intelligence is typically unaffected but may decline with disease progression. Intelligence is typically normal, although learning disabilities are common. Survival is usually past 25 years, and some live into their 50s. *Cause*: Mutations in the *ATM* gene (11q22.3). *Inheritance*: AR. Although those with heterozygous mutations in *ATM* still have an increased risk of cancer. *Prevalence*: 1:40,000–1:100,000 live births in the United States. *Treatment*: Variable responses to amantadine and 4-aminopyridine for myoclonus. IVIG (intravenous immunoglobulin) replacement therapy for those with frequent and severe infections and low IgG levels; aggressive pulmonary hygiene for those with chronic bronchiectasis; steroids temporarily improve neurologic function, but symptoms reappear within days of discontinuation; and avoidance of excessive ionizing radiation.

Genetic characterization of Italian patients with Bardet-Biedl syndrome and correlation to ocular, kidney and audio-vestibular phenotype: Identification of eleven novel pathogenic sequence variants. *BMC Medical Genetics*, 18(1), 10.

Batten disease *Disease category*: Neurological disorder. *Clinical features*: Typical development until rapid vision loss begins between 4–10 years; children become completely blind within 2–4 years of the onset of vision loss. Gradual onset of ataxia and myoclonic, generalized tonic-clonic or focal seizures happens between ages 9–18 years. Early death usually occurs by late teens or early 20s, although some patients have lived into their 30s. *Associated complications*: Gradual intellectual decline, spasticity, psychosis, kyphoscoliosis, decline in speech, behavioral problems, and sleep disturbance. *Cause*: Mutations in *CLN3*, *PPT1*, *TPP1*, *CLN9*, and *ATP13A2* are associated with juvenile neuronal ceroid-lipofuscinosis. *Treatment*: Antiepileptic drugs should be selected carefully. Lamotrigine had a favorable effect in studies, and benzodiazepenes may be beneficial for seizures, anxiety, spasticity, and sleep disorders. Trihexyphenyldil has improved dystonia and sialorrhea (drooling). Those with swallowing problems may require gastric tube placement. Some patients with *CLN3* disease may need antidepressants and antipsychotic agents. *Inheritance*: AR. *Incidence*:

1.3:100,000 to 7:100,000 live births. Many other forms of neuronal ceroid *lipofuscinosis* exist, including infantile, late infantile, juvenile, and adult forms. Mutations in 13 CLN genes cause various forms of neuronal ceroid lipofuscinosis.

biotinidase deficiency (late-onset multiple carboxylase deficiency) *Disease category:* Inborn error of metabolism: cofactor deficiency. *Clinical features:* A disorder characterized by varying degrees of intellectual disability, hypotonia, seizures (often infantile spasms), alopecia, skin rash, delayed myelination, and lactic acidosis; onset of symptoms usually occurs between 2 weeks and 2 years of age. *Associated complications:* Hearing and visual impairment, respiratory difficulties and apnea, and recurrent infections. *Cause:* Defects in various enzymes for biotin transport or metabolism; genetic mutations have been identified in *BTN* (3p25). *Inheritance:* AR. *Incidence:* 1:60,000–1:140,000. *Treatment:* Supplementation with oral biotin; response is better if used early in the course of the disease. When picked up by newborn screen and supplementation given early, children have a completely normal outcome.

Börjeson-Forssman-Lehmann syndrome *Disease category:* Multiple congenital anomalies. *Clinical features:*

Obesity, short stature, postpubertal gynecomastia (breast enlargement in males), large ears, coarse facial appearance, small external genitalia, eye anomalies, tapering fingers, and varying degree of intellectual disability. *Associated complications*: Seizures, abnormal head size ranging from microcephalic to macrocephalic, and hypotonia. *Cause*: Mutations in *PHF6* (Xq26.3). *Inheritance*: XLR, with females less severely affected than males. *Prevalence*: Rare.

References: De Winter, C. F., van Dijk, F., Stolker, J. J., & Hennekam, R. C. (2009). Behavioural phenotype in Borjeson-Forssman-Lehmann syndrome. *Journal of Intellectual Disability Research*, 53(4), 319–328.

Brachmann de Lange syndrome *See* de Lange syndrome.

Canavan disease (spongy degeneration of central nervous system) *Disease category*: Neurological disorder. *Clinical features*: Progressive neurological disorder consisting of macrocephaly, hypotonia progressing to spasticity with age, visual impairment, and early death. Symptoms begin at 3–6 months of age; children do not develop the ability to sit, walk, or talk. Despite limitations, children are interactive. *Associated complications*: Feeding difficulties with progressive swallowing problems, gastroesophageal reflux, severe intellectual disability, and head lag. *Cause*: Deficiency in the enzyme aspartoacylase caused by a mutation in *ASPA* (17pter–p13). *Inheritance*: AR. *Prevalence*: Rare in most populations; about 1:6,400–1:13,456 in the Ashkenazi Jewish population.

Carpenter syndrome (acrocephalosyndactyly, type II)

Disease category: Craniosynostosis. *Clinical features*: Craniosynostosis, flat nasal bridge, malformed and low-set ears, short digits, syndactyly and/or polydactyly, obesity, and hypogenitalism and/or cryptorchidism. *Associated complications*: Congenital heart defects and hearing loss; 75% have mild intellectual disability. *Cause*: Mutations in *RAB23*. Mutations in *MEGF8* have

more recently been linked to a subtype of Carpenter syndrome. *Inheritance*: AR. *Prevalence*: Rare.

References: Jenkins, D., Baynam, G., De Catte, L., Elcioglu, N., Gabbett, M. T., Hudgins, L., . . . Wilkie, A. O. (2011). Carpenter syndrome: Extended *RAB23* mutation spectrum and analysis of nonsense-mediated mRNA decay. *Human Mutation*, 32(4), E2069–E2078.

cerebrohepatorenal syndrome *See* Zellweger syndrome.

CHARGE syndrome *Disease category*: Multiple congenital anomalies. *Clinical features*: CHARGE is an acronym that stands for Coloboma (defect in iris or retina), Heart defect, choanal Atresia (congenital blockage of the nasal passages), Retarded growth and development, Genital anomalies, and Ear anomalies with or without hearing loss. *Associated complications*: Hypogenitalism, cryptorchidism, occasional cleft lip/palate, varying degrees of intellectual disability ranging from normal intelligence to profound intellectual disability, behavioral problems, and potentially severe visual and hearing impairments. Survival ranges widely, from 5 days to 46 years. *Cause*: Mutations in *CHD7* and *SEMA3E*. *Inheritance*: Majority of cases are caused by a NM, with evidence of AD inheritance when passed from an affected individual; associated with increased paternal age. Usually SP; approximately 8% of cases are familial. *Prevalence*: 1:8,500–1:12,000; more common in females than males.

chondroectodermal dysplasia *See* Ellis-van Creveld syndrome.

chromosome 22q11 deletion syndrome (includes phenotypes previously described as DiGeorge syndrome, velocardiofacial syndrome [VCFS], Shprintzen syndrome, conotruncal anomaly face syndrome, some cases of AD Opitz G/BBB syndrome, and Cayler cardiofacial syndrome) *Disease category*: Multiple congenital anomalies/contiguous

gene deletion. *Clinical features*: Congenital heart disease (especially conotruncal malformations, such as tetralogy of Fallot, interrupted aortic arch, ventricular septal defect, and truncus arteriosus), palatal abnormalities, characteristic facial features, learning disabilities, and immune deficiency. *Associated complications*: Feeding problems in infancy, hypocalcemia, kidney anomalies, hearing loss, laryngotracheoesophageal anomalies, growth hormone deficiency, rare seizures, hypernasal speech, psychiatric illness, developmental disabilities (ranging from learning disability to more significant cognitive delays), gross and fine motor delays, and expressive language delayed more significantly than receptive language. *Cause*: 1.5- to 3.0-Mb hemizygous deletion of chromosome 22q11.2. Haploinsufficiency of the *TBX1* gene in particular is responsible for most of the physical malformations. There is evidence that point mutations in the *TBX1* gene can also cause the disorder. *Inheritance*: AD; 93% from NM and 7% from an affected parent; one parent occasionally has a chromosomal rearrangement involving 22q, which increases the risk for recurrence; risk to offspring of affected individuals is 50%. *Prevalence*: 1:6,000 in Caucasians, African Americans, and Asians, and 1:3,800 in the Hispanic population in the United States.

Cornelia de Lange syndrome See de Lange syndrome.

craniofacial dysostosis See Crouzon syndrome.

cri-du-chat syndrome (chromosome 5p– syndrome)

Disease category: Multiple congenital anomalies/Contiguous gene syndrome. *Clinical features*: Prenatal and postnatal growth retardation, cat-like cry in infancy, hypertelorism with downward slant, microcephaly, low-set ears, micrognathia, single palmar crease, and cognitive deficits ranging from learning difficulties in some patients to moderate or severe intellectual disability in others. Receptive language skills are better than expressive language. *Associated complications*: Severe respiratory and feeding difficulties in infancy, hypotonia, inguinal (groin) hernias, occasional congenital heart defects, sleep disturbance, and hyperactivity. *Cause*: Partial deletion of chromosome 5p15.2; deletions can range from involving only the 5p15.2 band to the entire short arm. There is evidence that deletion of the telomerase reverse transcriptase (*TERT*) gene is specifically involved in the phenotypic changes. *Inheritance*: Usually NM; in 12% of cases a parent carries a balanced translocation. *Prevalence*: 1:20,000–1:50,000.

Crouzon syndrome (craniofacial dysostosis) *Disease category*: Craniosynostosis. *Clinical features*: Craniosynostosis, shallow orbits with proptosis (protuberant eyeballs), hypertelorism (widely spaced eyes), strabismus, parrot-beaked nose, short upper lip, maxillary hypoplasia (small upper jaw), and conductive

hearing loss. *Associated complications:* Increased intracranial pressure, intellectual disability, seizures, visual impairment, agenesis of the corpus callosum, occasional cleft lip or palate, and obstructive airway problems. Some children with Crouzon have acanthosis nigricans (a skin condition characterized by areas of dark velvety discoloration in body folds and creases). *Cause:* Mutations in *FGFR2* (10q25.3–q26). Those with Crouzon with acanthosis nigricans have mutations in *FGFR3*. *Inheritance:* AD with variable expression; up to 25% may represent new mutations. *Prevalence:* Unknown.

de Lange syndrome (Brachmann de Lange syndrome, Cornelia de Lange syndrome) *Disease category:* Multiple congenital anomalies. *Clinical features:* Prenatal growth retardation, postnatal short stature, hypertrichosis (excessive body hair), synophrys (confluent eyebrows), anteverted nostrils, depressed nasal bridge, long philtrum (vertical indentation in the middle area of the upper lip), thin upper lip, microcephaly, low-set ears, limb and digital anomalies, and eye problems (myopia, ptosis, or nystagmus). *Associated complications:* Intellectual disability ranging from mild learning disabilities to severe impairments, behavioral problems, occasional heart defect, gastrointestinal problems, features of autism, self-injurious behavior, and occasional hearing loss. *Cause:* Mutations in *NIPBL* (3q26.3) are found in 60% of cases. Mutations in *SMC1A* (Xp11.22–p11.21), *SMC3* (10q25.2), *RAD21* (8q24.11), and *HDAC8* (Xq13.1) have been identified in a small percentage of individuals. A mild version of Cornelia de Lange has been associated with the *SMC3* gene. *Inheritance:* AD or XL; 99% NM. *Prevalence:* Published estimates range from 1:10,000–1:100,000.

DiGeorge syndrome *See* chromosome 22q11 micro-deletion syndromes.

DMD muscular dystrophy, Duchenne type *See* muscular dystrophy, Duchenne and Becker types.

Down syndrome *Disease category:* Chromosome abnormality/multiple congenital anomalies. *Clinical features:* Hypotonia, flat facial profile, upward-slanting palpebral fissures, small ears, small nose with low nasal bridge, single palmar crease, short stature, intellectual disability, and congenital heart disease. *Associated complications:* Atlantoaxial (upper cervical spine) instability; hyperextensible large joints; strabismus; thyroid dysfunction; predisposition toward immune disorders and leukemia; eye abnormalities, including strabismus, nystagmus, cataracts, and glaucoma; narrow ear canals and high incidence of middle-ear infections with potential hearing loss; and neurological abnormalities, including risk of seizures and early-onset Alzheimer's disease. *Cause:* Extra chromosome 21 caused by trisomy, mosaicism, or translocation. *Inheritance:* NM; usually nondisjunction chromosomal abnormality. Recurrence risk in the absence of translocation is 1%–2% in women younger than 35 years and the same as the typical maternal age-related risk in women over 35 years of age at delivery. If translocation is present in parent, recurrence risk is higher and is dependent on sex of carrier parent. *Prevalence:* 1:100,000–1.5:100,000. *Incidence:* 1:800 births. *See* Chapter 15.

Dubowitz syndrome *Disease category:* Multiple congenital anomalies. *Clinical features:* Prenatal onset of growth deficiency, postnatal short stature, eczema, sparse hair, mild microcephaly, cleft palate, and dysmorphic facial features, including high forehead, broad nasal bridge, ptosis, and epicanthal folds. *Associated complications:* Intellectual disability, behavioral disturbances, recurrent infections, increased frequency of malignancy, occasional hypospadias (abnormality in the location of the male urethra) or cryptorchidism, and hypoparathyroidism. *Cause:*

Unknown. Likely genetic heterogeneous with phenotypic overlap. *Inheritance*: AR. *Prevalence*: Rare.

Ehlers-Danlos syndrome (EDS) *Disease category*: Connective tissue disorder. *Clinical features*: At least 10 distinct forms have been described. All include aspects of skin fragility, easy bruisability, joint hyperextensibility, and hyperelastic skin. The classic (previously type I and II) and hypermobility (previously type III) forms are most commonly described and have similar clinical presentations with the previously mentioned features; the vascular form (previously type IV) is characterized by severe blood vessel involvement with risk of spontaneous arterial rupture; the progeroid (premature aging) form is characterized by wrinkled face, curly/fine hair, scanty eyebrows and eyelashes, and periodontitis in addition to the other usual signs of EDS; type V has been questioned as to whether it is actually a distinct phenotype; the kyphoscoliotic (type VI) form is characterized by eye involvement, including corneal fragility and kyphoscoliosis (curvature of the spine); the arthrochalasia type (type VIIA and VIIB) presents with congenital bilateral hip dislocation; the dermatosparaxis type (previously type VIIC) includes delayed closure of the fontanelles, characteristic facies, edema of the eyelids, blue sclerae, and short stature and fingers; the periodontitis type (previously type VIII) includes periodontal disease; and the cardiac valvular form has the typical signs as well as cardiac valvular defects. *Associated complications*: Hypotonia, delayed gross motor milestones, chronic pain, premature loss of teeth, mitral valve prolapse, intestinal hernias, premature delivery from premature rupture of membranes, scoliosis, and abnormalities of thymus. *Cause*: Each form is associated with an abnormality in the formation of collagen. The classic form is caused by mutations in the *COL5A1* and *COL5A2* genes; the hypermobility form is caused by

mutations in the *COL3A1* gene as well as the tenascin XB gene (*TNXB*); the vascular type is caused by mutations in the *COL3A1* gene; the progeroid form is caused by mutations in the *B4GALT7* gene; mutations in the lysyl hydroxylase gene (*PLOD*) cause some cases of kyphoscoliotic form; the arthrochalasia type is caused by mutations in the *COL1A1* and *COL1A2* genes; the dermatosparaxis type is linked to the *ADAMTS2* gene; and the cardiac valvular type is linked to *COL1A2*. A possible new form of EDS was discovered in 2010 that is like the kyphoscoliotic form but without lysyl hydroxylase deficiency; it has been linked to the gene *CHST14*. *Inheritance*: The classic, hypermobility, vascular, arthrochalasia, and periodontitis types are all AD. Progeroid, kyphoscoliotic, dermatosparaxis, and cardiac valvular are all AR. *Prevalence*: Classic type is 1:20,000; hypermobility type ranges from 1:5,000–1:20,000; kyphoscoliotic form is estimated at around 1:100,000; vascular type is 1:250,000; and the rest are unknown.

FAE See fetal alcohol effects.

familial dysautonomia (Riley-Day syndrome) *Disease category:* Neurological disorder. *Clinical features:* Absent or sparse tears, absence of fungiform papillae (knoblike projections) on the tongue, diminished pain and temperature sensation, postural hypotension, abnormal sweating, episodic vomiting, swallowing disorder, ataxia, and decreased reflexes. *Associated complications:* Feeding difficulties, scoliosis, joint abnormalities, hypertension, hypotonia, delay in motor milestones, and aseptic necrosis of bones (damage to bony tissue unassociated with infection or injury). Neuronal degeneration is progressive. *Cause:* Mutation of the *ELP1* (previously *IKBKAP*) gene (9q31–q33). Two common mutations in the Ashkenazi Jewish population. *Inheritance:* AR. *Prevalence:* Rare; 1:36 carrier frequency in the Ashkenazi Jewish population.

FGDY facio-genital dysplasia See Aarskog-Scott syndrome.

FMR1-related disorders (fragile X syndrome, fragile X-associated tremor/ataxia syndrome [FXTAS], and FMR1-related primary ovarian insufficiency [POI]) *Disease category:* Neurological disorder/triplet repeat expansion. *Clinical features:* Males with full mutations typically have a large head, long face, prominent forehead and chin, protruding ears, behavioral problems such as hyperactivity, hand flapping, hand

biting, temper tantrums, and sometimes autism. *Associated complications:* Abnormalities of connective tissue with finger joint hypermobility or joint instability, mitral valve prolapse, and large testes. Females heterozygous for full-mutation alleles can have similar phenotypes as males but with lower frequency and generally milder involvement. Both males and females with premutations are known to develop FXTAS/late-onset progressive cerebellar ataxia and intention tremor; 21% of females who are carriers of premutation alleles develop primary ovarian insufficiency (cessation of menses before age 40). *Cause:* Mutation in *FMR1* gene on Xq27–q28; molecular analysis reveals an increase in cytosine-guanine-guanine (CGG) trinucleotide repeats in the coding sequence of the *FMR1* gene. Normal allele sizes vary from 6 to approximately 55 CGG repeats. Phenotypically unaffected individuals have premutations, with an allele size ranging from 55 to 200, but are at risk for FXTAS and POI. Allele sizes of greater than 200 CGG repeats generally indicate a full mutation with phenotypic expression of the syndrome. *Inheritance:* X-linked with genetic imprinting (full mutations are not inherited from the father) and anticipation (number of repeats may increase in subsequent generations). *Prevalence:* 16:100,000–25:100,000 males; prevalence of females affected with fragile X is presumed to be half the male prevalence. See also Chapter 15.

Friedreich ataxia *Disease category:* Neurological disorder/triplet repeat expansion. *Clinical features:* Slowly progressive neurological disorder characterized by limb and gait ataxia, dysarthria, nystagmus, pes cavus (high-arched feet), hearing loss, and kyphoscoliosis (backward curve of the spine). In rare cases, progression is rapid. Onset is usually between ages 10–15. *Associated complications:* Delayed motor milestones, cardiomyopathy (heart muscle weakness),

and/or congestive heart failure; increased risk of insulin-dependent diabetes mellitus; and impaired color vision. Cognition is not typically affected; however, difficulties with motor planning, concept formation, visuospatial reasoning, attention/working memory, cognitive flexibility, and reduced speed of information processing are common. *Cause*: Usually homozygous guanine-adenosine-adenosine (GAA) expansions in intron 1 of the frataxin (*FXN*) gene on chromosome 9q13; point mutations in the *FXN* gene have also been identified. Normal alleles are 5–33 GAA repeats; premutation alleles are 34–65 uninterrupted GAA repeats; full disease-causing alleles are 66–1700 GAA repeats. *Inheritance*: AR. *Prevalence*: Approximately 2:100,000–4:100,000. *Treatment*: Supportive care includes physical therapy, orthopedic surgery to correct progressive scoliosis, and close cardiology follow-up. Many different possible treatments are being actively studied.

G syndrome See Opitz GBB syndrome.

GBS See Guillain-Barre syndrome.

galactosemia *Disease category*: Inborn error of metabolism: carbohydrate. *Clinical features*: Jaundice, lethargy, and hypotonia in the newborn period; poor weight gain with vomiting and diarrhea; bleeding diathesis; cataracts; liver dysfunction or failure if disease untreated; varying degrees of intellectual impairment (severe if diseases untreated); visual-perceptual impairments; and verbal dyspraxia. *Associated complications*: Ovarian failure, hemolytic anemia, increased risk of sepsis (particularly *Escherichia coli* in the neonate), cerebellar ataxia, tremors, and choreoathetosis (movement disorders). Implementing a galactose-free diet in the newborn period prevents liver failure, sepsis, severe intellectual disability and death, but even when treated, children still experience some cognitive deficits, speech defects, cataracts, and ovarian failure (females). There is a clinical variant galactosemia (p.Ser135Leu/Ser135Leu genotype) that occurs in African Americans and Africans, which,

when treated, does not develop the typical long-term complications including premature ovarian failure. Some newborns have a mild variant of galactosemia (Duarte galactosemia), which is not associated with developmental delays, cataracts, or hepatocellular damage. Nutritional intervention is not usually necessary or is needed only in children under 1 year of age, although there is no uniform standard of care for patients with Duarte galactosemia. *Cause*: Most commonly caused by a deficiency of the enzyme galactose-1-phosphate uridylyltransferase or GALT (9p13). It also can be caused by a deficiency of galactokinase (GALK) or galactose epimerase (GALE). (They are all enzymes required for digestion of galactose, a natural sugar found in milk). *Inheritance*: AR. *Prevalence*: 1:10,000–1:30,000 in the United States. *Treatment*: Galactose-free diet.

Gaucher disease *Disease category*: Inborn error of metabolism: lysosomal storage disease. *Clinical features*: Three clinically distinct forms, the most common of which (type 1) has onset in adulthood and includes enlarged spleen and liver, anemia, thrombocytopenia (low platelet count), and bone involvement; it is distinguished by the lack of neurological involvement. Most individuals with type 1 go undiagnosed. Type 2 presents in infancy with an enlarged spleen, hematological abnormalities, bony lesions, abnormalities of skin pigmentation, limited psychomotor development, and a rapidly progressive course. Most children will die within the first 2–4 years of life. Type 3 is more variable, with ataxia, seizures, eye movement disorder, and dementia, with onset before age 2 years but with a more slowly progressive course. There is also a perinatal lethal form associated with ichthyosiform (rough, thick, and scaly skin) or collodion (a tight shiny membrane that resembles plastic wrap) skin abnormalities and nonimmune hydrops fetalis (accumulation of fluid, or edema, in the fetus). *Associated complications*: Rare associated features such as cardiac valvular involvement and Parkinsonian features have been associated with specific genotypes. *Cause*: Accumulation of glucosylceramide due to deficiency of the enzyme beta-glucosidase from mutations in the *GBA* gene on chromosome 1q21. *Inheritance*: AR. *Prevalence*: Rare in the general population; prevalence of type 1

estimated to be approximately 1:855 in the Ashkenazi Jewish population. *Treatment:* Enzyme replacement therapy (ERT) improves rate of bone loss and reduces spleen size but does not seem to affect neurological symptoms; thus, it is generally used only in individuals with type 1. For those where ERT is not an option (due to allergy, hypersensitivity, or poor venous access), substrate reduction therapy is an option. Bone marrow transplantation has been used in those with more severe disease, usually type 3.

globoid cell leukodystrophy See Krabbe disease.

glutaric acidemia, type I *Disease category:* Inborn error of metabolism: organic acidemia. *Clinical features:* Macrocephaly, hypotonia, basal ganglia lesions causing a movement disorder (dystonia), and seizures present between 6–18 months of age, interrupting otherwise typical development. This disorder may mimic dyskinetic cerebral palsy. *Associated complications:* Episodic acidosis, vomiting, lethargy, and coma. Intellectual disability is usual if a basal ganglia lesion occurs; otherwise intellectual functioning may remain intact. *Cause:* Mutations in *GCDH* (chromosome 19p13.2) resulting in accumulation of glutaric acid and, to a lesser degree, of 3-hydroxyglutaric and glutaconic acids. *Inheritance:* AR. *Prevalence:* Overall frequency is 1:100,000; 1:30,000 in Sweden; and 1:50,000 in the United States. It is more common in certain ethnic groups such as in the Amish population. *Treatment:* Low-protein diet and supplemental oral carnitine. Early treatment results in significantly improved outcome, and the disorder is on newborn screening panels in many countries.

glutaric acidemia, type II (multiple acyl-CoA dehydrogenase deficiency) *Disease category:* Inborn error of metabolism: organic acidemia. *Clinical features:* Severe metabolic acidosis, hypoglycemia, and cardiomyopathy; urine with a characteristic odor of sweaty feet, similar to that present in isovaleric acidemia. Dysmorphic facial features (macrocephaly, large anterior fontanelle [soft spot], high forehead, flat nasal bridge, and malformed ears) are seen in one half of cases. This condition also can present later in life with episodic vomiting, acidosis, and hypoglycemia. *Associated complications:* Muscle weakness, liver disease, cataracts, respiratory distress, and kidney cysts. *Cause:* Mutations in at least three different genes—*ETFA*, *ETFB*, and *ETFDH*—have been identified. No clinical differences with respect to causative gene have been identified. *Inheritance:* AR. *Prevalence:* Rare. *Treatment:* Diet with supplemental riboflavin and carnitine.

glycogen storage diseases (glycogenoses) *Disease category:* Inborn error of metabolism: carbohydrate. *Clinical features:* More than 12 forms of glycogen storage diseases are currently known, all caused by defects in the production or breakdown of glycogen and resulting in a wide spectrum of clinical features. They share varying degrees of liver and muscle abnormalities and can be broken down by whether they primarily affect the muscle (and therefore present with muscle cramps, easy fatigability, and progressive muscle weakness) or the liver (where an enlarged liver and decreased blood sugar are the initial symptoms). In all disease forms, patient organs have excessive glycogen accumulation. Types I (glucose-6-phosphate deficiency), II (Pompe disease, acid alpha-glucosidase deficiency), III (amylo-1, 6-glycosidase deficiency), and VI (hepatic phosphorylase deficiency) are the most common and represent almost 95% of cases. Common clinical features include hypoglycemia, short stature, enlarged spleen, and muscle weakness. *Associated complications:* Hypotonia, kidney abnormalities, gouty arthritis, bleeding abnormalities, hypertension,

and respiratory distress; type II disease characteristically has severe cardiac, muscle, and neurological involvement. *Cause*: Deficiencies in the various enzymes involved in the synthesis and degradation of glycogen. There are many genes and chromosome locations associated with glycogenoses. *Inheritance*: All except type IX (previously type VIII) are inherited as AR; type IX is XLR. *Prevalence*: Combined incidence of 1:20,000–1:25,000. *Treatment*: Increased protein intake and overnight tube feeding of cornstarch to maintain normoglycemia have been shown to be useful for supportive care. This treatment also prevents growth and developmental problems and can improve the biochemical abnormalities. Enzyme replacement therapy is available for Pompe disease. Liver transplantation has been attempted in types I, III, and IV, with correction of the biochemical abnormalities but not all sequelae.

GM2 gangliosidosis, type I See Tay-Sachs disease.

Goldenhar syndrome See oculo-auriculo-vertebral spectrum.

Guillain-Barré Syndrome (GBS) *Disease category*: Neuromuscular disease. *Clinical features*: GBS is an acute inflammatory demyelinating polyneuropathy. There is pain and the development over one to several days of muscle weakness, with the inability to walk and a loss of deep tendon reflexes. The weakness affects both sides of the body symmetrically, usually starting in the lower extremities. The arms are involved later, with maximum weakness occurring by 3 weeks. Most children with GBS begin to recover 2–3 weeks after the symptoms begin. About 85% of affected children are able to walk within 6 months; however, some have residual weakness. The mortality rate is 3%, and the chance of relapse has been reported as 7% in children. *Cause*: It can follow an upper respiratory or gastrointestinal (GI) viral infection. A specific type of GI infection produced

by the bacteria *Campylobacter jejuni* has been particularly associated with GBS. GBS is considered an autoimmune disease. Although rare familial cases have been reported, it is thought to be a multifactorial disease with both genetic and environmental factors contributing to its occurrence. *Incidence*: 0.4–1.7 cases per 100,000 people each year. *Diagnosis*: Spinal fluid analysis and electromyographic evaluation. *Treatment*: Treatment is mostly supportive. About 10%–20% need to be placed on a ventilator. Medical treatment includes the use of intravenous immune globulin (IVIG) and/or plasmapheresis.

Hallermann-Streiff syndrome (oculo-mandibulo-dyscephaly with hypotrichosis) *Disease category*: Skeletal dysplasia. *Clinical features*: Proportionate short stature; characteristic facial appearance, including small eyes, small, pinched nose, and small mouth; sparse, thin hair; and frontal bossing (prominent central forehead). *Associated complications*: Various eye abnormalities, including nystagmus, strabismus, cataracts, and/or decreased visual acuity; neonatal teeth and other dental abnormalities; narrow upper airway or tracheomalacia (softening of the tracheal cartilages), with related respiratory difficulty; frequent respiratory infections, snoring, and feeding difficulties; clinical overlap with oculo-dento-digital dysplasia (ODDD) has been suggested; and intellectual disability has been reported in some cases. *Cause*: Unknown, believed to be genetic; one patient has been identified with a homozygous mutation in the *GJA1* gene known to be causative in ODDD. *Inheritance*: Most reported cases are not inherited from an affected parent and are assumed to be caused by an NM. *Prevalence*: Rare.

hemifacial microsomia See oculo-auriculo-vertebral spectrum.

hereditary progressive arthro-ophthalmopathy See Stickler syndrome.

holocarboxylase synthetase deficiency *Disease category:* Inborn error of metabolism: cofactor deficiency. *Clinical features:* Disorder of biotin metabolism characterized by seizures, hypotonia, lethargy, coma, skin rash, alopecia (loss of hair from skin areas where it is normally present), and acidosis typically presenting before 3 months. Often, the presenting feature is feeding difficulty or respiratory distress. *Associated complications:* Intellectual disability, hearing impairment, optic atrophy with visual impairment, recurrent infections, and vomiting. *Cause:* Mutations in *HCLS* (21q22.13) causing enzyme deficiencies of holocarboxylase synthetase or 3-methylcrotonyl-CoA carboxylase. *Inheritance:* AR. *Prevalence:* Rare. *Treatment:* Oral biotin supplementation. Prenatal treatment with oral biotin corrects lethargy, hypotonia, and vomiting.

holoprosencephaly (HPE) *Disease category:* Malformation. *Clinical features:* This classification encompasses a spectrum of midline defects of the brain and face that occur after failed or abbreviated midline cleavage of the developing brain during the third to fourth week of gestation. The most severe defects are incompatible with life. Individuals who survive have varying degrees of disability, ranging from typical development with hypotelorism (widely spaced eyes) to alobar holoprosencephaly (brain without segmentation into hemispheres) and cyclopia (single central eye). *Associated complications:* Seizures, endocrine abnormalities, micropenis and other genital anomalies, cleft of retinae, and intellectual disability. Facial anomalies are seen in 80% of cases. *Cause:* There are environmental and genetic causes for holoprosencephaly. Infants of diabetic mothers have a 200-fold increase risk for holoprosencephaly. Other, less clearly seen associations in animal models include alcohol and retinoic acid, cholesterol-lowering agents, and maternal hypocholesterolemia; 25%–50% of individuals with HPE have a chromosomal abnormality such as trisomy 13, 18, and triploidy. Copy number variants and large structural chromosomal abnormalities have also been documented. The rest have a pathogenic variant in a single

gene; mutations in *SHH* (7q36) is the most common cause, followed by mutations in *ZIC2* (13q32); *SIX3* (2p21); *TGIF1* (18p11.3); and many other rare related genes, including *GLI2* (2q14), *PTCH1* (9q22.3), *DISP1* (1q42), *FGF8* (10q24), *FOXH1* (8q24.3), *NODAL* (10q22.1), *TDGF1* (3p23-p21), *GAS1* (9q21.33), *DLL1* (6q27), and *CDON* (11q24.2). *Inheritance:* May be part of a syndrome or caused by teratogenic exposure; as an isolated birth defect, may be AD or AR. *Prevalence:* 1:250 gestations, but 1:10,000 live births.

Holt-Oram syndrome *Disease category:* Multiple congenital anomalies. *Clinical features:* Upper-limb defect ranging from hypoplastic (incompletely formed), abnormally placed, or absent thumbs to hypoplasia of the radius, ulna, or humerus (arm bones) and complete phocomelia (foreshortened limbs); 75% of affected individuals also have a congenital heart defect (atrial septal defect and ventricular septal defect are most common). *Associated complications:* Occasional abnormalities of chest muscles and vertebral anomalies. *Cause:* Mutations in *TBX5* (12q2). Recent study showed mutations in *SALL4* may also cause Holt-Oram. *Inheritance:* AD with variable expression. *Prevalence:* Approximately 1:100,000.

References: Baban, A., Pitto, L., et al. (2014). Holt-Oram syndrome with intermediate atrioventricular canal defect, and aortic coarctation: functional characterization of a de novo *TBX5* mutation. *American Journal of Medical Genetics, Part A*, 164A, 1419–1424.

homocystinuria *Disease category:* Inborn error of metabolism: amino acid. *Clinical features:* Downward dislocation of lens of the eye (ectopia lentis) and/or myopia; tall, slim physique; scoliosis; risk for thromboembolism; and developmental delay/intellectual disability. Two forms have been described, differing in their responsiveness to pyridoxine (vitamin B6).

Associated complications: Behavioral disorders, cataracts or glaucoma, and osteoporosis. **Cause:** Mutations in CBS (21q22). **Inheritance:** AR with variable expressivity. **Incidence:** Ranges from 1:65,000 in Ireland to 1:344,000 worldwide. **Treatment:** Folic acid and vitamin B12 supplementation, use of betaine, and dietary restriction of methionine. Pyridoxine is used in the rare individuals who have the pyridoxine-responsive form of the disease. Early treatment with pyridoxine in responsive cases may allow typical intelligence. Treatment with above agents significantly reduces the risk of vascular events.

Hunter syndrome (MPS II) See mucopolysaccharidoses (MPS).

Huntington disease (HD; previously called Huntington chorea), juvenile *Disease category:* Neurologic/triplet repeat expansion. *Clinical features:* Juvenile onset progressive neurological disorder. For cases to be considered juvenile HD, onset must occur by 20 years of age. Children present with dysarthria, clumsiness, hyperreflexia, rigidity, and oculomotor disturbances. *Associated complications:* Joint contractures, swallowing dysfunction, and seizures. *Cause:* Expansion of cytosine-adenine-guanine (CAG) trinucleotide repeat in *HTT* (4p16.3). Normal number of CAG repeats is 11–34; individuals affected with juvenile HD have greater than 60 CAG repeats. *Inheritance:* AD with anticipation (earlier onset with each generation, especially when paternally inherited). Progression in children with paternally inherited disease is more rapid than in children with maternally inherited disease. *Prevalence:* 3:100,000–7:100,000 in populations of western European descent. Less frequent in other populations. Juvenile onset disease accounts for 5%–10% of all cases of HD.

Hurler syndrome (MPS IH) See mucopolysaccharidoses (MPS).

hypophosphatasia *Disease category:* Skeletal dysplasia. *Clinical features:* A disorder of calcium and phosphate metabolism with symptoms ranging from a severe infantile form (which can be rapidly fatal) to a relatively mild childhood form. A total of six forms of the disease have been described (perinatal lethal, perinatal benign, infantile, childhood, adult, and odonto-hypophosphatasia [dental only]). Features include short stature, bowed long bones, craniosynostosis, and hypocalcemia. *Associated complications:* Seizures, multiple fractures, and premature loss of teeth. The perinatal lethal form presents as short limbs and poor ossification (bone formation) of the skeleton, and affected infants usually die from pulmonary insufficiency. The benign perinatal form is usually identified by prenatal ultrasound, but the skeletal manifestations slowly resolve with an eventual phenotype similar to the childhood or adult types. The childhood form presents with an early loss of secondary teeth, short stature, and delayed walking with a waddling gait. Joint pain and non-progressive muscle weakness may also be present and the features resemble rickets. *Cause:* Mutations in *ALPL* (1p36). *Inheritance:* AR (severe forms), AR/AD (milder forms). *Incidence:* 1:100,000–1:300,000; incidence of severe infantile form is 1:2500 in Menonite families from Manitoba, Canada.

incontinentia pigmenti *Disease category:* Dermatologic disorder. *Clinical features:* Swirling patterns of hyperpigmented skin lesions; tooth abnormalities;

microcephaly; ocular abnormalities; thin, wiry hair; hairless lesions; and intellectual disability in approximately one third of cases. *Associated complications:* Spasticity, seizures, and vertebral or rib abnormalities, as well as strabismus, hydrocephalus, and a history of male miscarriages. *Cause:* Mutations in *IKBK*G (previously *NEMO*) gene (Xq28), skewed X-inactivation. A deletion of exons 4–10 is present in about 80% of affected individuals. *Inheritance:* XLD with lethality in males. Living affected males have been found with the 47, XXY karyotype or somatic mosaicism. *Prevalence:* Rare.

infantile Refsum disease See Refsum disease, infantile.

isovaleric acidemia *Disease category:* Inborn error of metabolism: organic acidemia. *Clinical features:* A disorder of organic acid metabolism; an acute, often fatal neonatal form is characterized by acidosis and coma; a chronic form presents with recurrent attacks of ataxia, vomiting, lethargy, and ketoacidosis. Attacks are generally triggered by infection or increased protein load. Urine smell of sweaty feet is characteristic. *Associated complications:* Seizures, intellectual disability if untreated, enlarged liver, vomiting, and hematologic abnormalities. *Cause:* Mutations in *IVD* (15q15.1) lead to deficiency of the enzyme isovaleryl-CoA dehydrogenase. *Inheritance:* AR. *Prevalence:* Rare. *Treatment:* Treatment consisting of a low-protein diet with supplemental oral glycine and carnitine has resulted in a relatively good cognitive outcome.

Joubert syndrome *Disease category:* Multiple congenital anomalies. *Clinical features:* Structural cerebellar abnormalities (“molar tooth sign” on MRI),

hypotonia in infancy that develops into ataxia, abnormal eye movements, retinal dysplasia or coloboma, abnormal breathing pattern, and developmental delay/intellectual disability and behavioral problems; characteristic facial appearance, including large head, prominent forehead, ptosis, epicanthal folds, upturned nose, and tongue protrusion. *Associated complications:* Retinal dystrophy, kidney disease, ocular colobomas, occipital encephalocele, hepatic fibrosis, polydactyly, oral hamartomas (benign tumors), and endocrine abnormalities. Cognitive ability ranges from moderate to severe intellectual disability. *Cause:* Joubert syndrome has been linked to 34 different genes. *Inheritance:* AR or XLR. *Prevalence:* Rare.

juvenile neuronal ceroid lipofuscinosis See Batten disease.

Kabuki syndrome *Disease category:* Multiple congenital anomalies. *Clinical features:* Microcephaly, trapezoid philtrum (area between base of nose and upper lip), prominent posteriorly rotated ears, preauricular pit (small hole/indentation on the ear), long palpebral fissures (the opening between the eye lids), thick eyelashes, ptosis, sparse and broad arched eyebrows, congenital heart defect, hirsutism (excessive hair), café au lait spots, cryptorchidism (undescended testes), small penis, hypotonia, and joint hyperextensibility. *Associated complications:* Cleft palate, recurrent ear infections, hearing loss, aspiration pneumonia, feeding difficulties, malabsorption, anal stenosis (stricture), imperforate anus, scoliosis, congenital hip dislocation, increased susceptibility to infections, seizures, intellectual disability, premature thelarche (breast development), hemolytic anemia, and congenital hypothyroidism. *Cause:* Mutations in *KMT2D* (formerly *MLL2*) (12q13.12) and *KDM6A* (Xp11.3). *Inheritance:* AD/XLR. *Prevalence:* Rare. Prevalence in Japan has been estimated at 1:32,000; birth incidence in Australia and New Zealand has been calculated at 1:86,000.

kinky hair syndrome See Menkes syndrome.

Klinefelter syndrome (KS; XXY syndrome) *Disease category:* Chromosomal abnormality. *Clinical features:* Occurs only in males. Males with KS have tall, slim stature; long limbs; relatively small penis and testes; and gynecomastia (breast enlargement) in 40%. *Associated complications:* Intention tremor (involuntary trembling arising when attempting a voluntary, coordinated movement) in 20%–50%, learning disabilities and delayed speech and language development, infertility, behavioral disorders, scoliosis, osteoporosis and reduced muscle strength, and vascular problems; 8% have diabetes mellitus as adults and risk of extragonadal midline germ cell tumors. Patients may appear to have no physical changes prior to puberty with the exception of long legs. *Cause:* Chromosomal nondisjunction resulting in the 47, XXY karyotype. *Inheritance:* NM caused by the presence of an additional X chromosome; about 50% of cases caused by maternal nondisjunction (error in the separation of chromosomes), while 50% are caused by paternal nondisjunction. *Prevalence:* 1:500–1:1,000 newborn males. *Treatment:* Hormone treatment is needed in adolescence for the development of secondary male sex characteristics.

Klippel-Feil syndrome *Disease category:* Multiple congenital anomalies. *Clinical features:* Cervical vertebral

fusion present at birth, hemivertebrae (incomplete development of one side of one or more vertebrae). *Associated complications:* Congenital scoliosis; torticollis (wry neck); low hairline; limited range of motion; sacral agenesis (absence of tailbone); hearing loss; occasional congenital heart defect; extra, fused, or missing ribs; middle-ear abnormalities; genitourinary abnormalities; and pain. *Cause:* Mutations in *GDF6* (8q22.2), *GDF3* (12p13.31), and *MEOX1* (17q21.31). *Inheritance:* AD for those with mutations in *GDF6* and *GDF3*. AR if caused by mutation in *MEOX1*. *Incidence:* Approximately 1:40,000, with a slight female predominance.

References: Kenna, M. A., Irace, A. L., Strychowsky, J. E., Kawai, K., Barrett, D., Manganella, J., & Cunningham, M. J. (2018). Otolaryngologic manifestations of Klippel-Feil syndrome in children. *JAMA Otolaryngology-Head & Neck Surgery*, 144(3), 238–243.

Klippel-Trenaunay-Weber syndrome (Klippel-Trenaunay syndrome) *Disease category:* Multiple congenital anomalies. *Clinical features:* Asymmetric hypertrophy of limb, face (lips, cheeks, tongue, teeth), or other body parts; hemangiomas (benign congenital tumors made up of newly formed blood vessels); and arteriovenous fistulas. *Associated complications:* Dependent on the area of hypertrophy; complications may affect any organ/body part, including the spinal cord (resulting in weakness or paralysis), kidneys (renal obstruction), and brain (intracranial hypertension). *Cause:* Some have mutations in the *PIK3CA* gene, making it part of the *PIK3CA*-related overgrowth spectrum (PROS). Likely other genes are involved that have yet to be identified. *Inheritance:* Believed to be passed on as an AD trait, where individuals are not affected unless a second, somatic mutation (arising after fertilization) occurs. *Prevalence:* Unknown.

Krabbe disease (globoid cell leukodystrophy) *Disease category:* Progressive neurologic disorder. *Clinical features:* In the classic form, symptoms begin before 6 months of age with irritability, progressive stiffness,

optic atrophy, cognitive deterioration, and early death, often before 2 years of age. Approximately 10%–15% of cases have onset of symptoms between 6 months and 17 years of age and have slower disease progression. *Associated complications:* Hypertonicity, opisthotonos (back arching), visual and hearing impairment, episodic unexplained fevers, and seizures; peripheral neuropathy. *Cause:* Deficiency of the galactocerebrosidase enzyme resulting from mutations in *GALC* (14q24.3–q32.1). *Inheritance:* AR. *Incidence:* 1:100,000; may be increased in specific populations such as the Druze kindred in Israel (carrier frequency of 1:6). *Treatment:* Hematopoietic stem cell transplantation seems to improve developmental outcome, although it has a high mortality rate.

Landau-Kleffner syndrome (LKS) *Disease category:* Neurologic. *Clinical features:* Normal development until ages 5–8 years, beginning with acquired aphasia (loss of speech) and regression in receptive language ability. Seizures are common in 70% of patients (usually atypical absence seizures). *Associated complications:* EEG abnormalities usually are continuous spike-and-wave in sleep (CSWS). Some patients show autistic features and issues with attention. *Cause:* Mutations in *GRIN2A* (16p13.2) have been found in 4.8%–7.7% of patients. Now considered part of the *GRIN2A*-related speech disorder and epilepsy syndromes. *Inheritance:* AD. *Prevalence:* Unknown. *Treatment:* Treatment of seizures with antiepileptic medications. See Chapter 22.

Laurence-Moon-Bardet-Biedl syndrome See Bardet-Biedl syndrome.

Leber congenital amaurosis *Disease category:* Ophthalmologic. *Clinical features:* Severe visual impairment

or blindness presenting in infancy, usually before the age of 6 months. Electroretinogram (ERG) responses are usually nonrecordable. *Associated complications:* High hypermetropia (farsightedness), photophobia (sensitivity to light), oculodigital sign (poking/rubbing/pressing of the eyes), keratoconus (thinning of the cornea), cataracts, and a variable appearance to the fundus. Rarely has been associated with developmental delay or intellectual disability. *Cause:* Mutations in 24 different genes. *Inheritance:* Mostly AR, rarely AD. *Prevalence:* 2:100,000–3:100,000. *Treatment:* There is an FDA-approved gene therapy medication (Luxturna) for those with mutations in *RPE65*.

Lennox-Gastaut syndrome See Chapter 22.

Lesch-Nyhan syndrome *Disease category:* Inborn error of metabolism: nucleic acid. *Clinical features:* An inborn error of purine metabolism associated with elevated levels of uric acid in blood and urine. Affected males appear symptom free at birth but then present with hypotonia and developmental delay during the first year of life. Dystonia (abnormal movements) and spasticity develop, accompanied by severe involuntary self-injurious behavior, including biting of fingers, arms, and lips. *Associated complications:* Cognitive impairment, seizures in 50%, hematuria (blood in urine), kidney stones, and ultimate kidney failure without treatment. *Cause:* Defect in enzyme hypoxanthine-guanine phosphoribosyl transferase caused by a mutation in *HPRT* (Xq26–q27.2). *Inheritance:* XLR. Affected females with skewed X-inactivation have been reported. Carrier females are typically unaffected, although some have increased uric acid excretion. *Prevalence:* 1:380,000. *Treatment:* Allopurinol is useful in preventing kidney and joint deposition of uric acid. Spasticity is treated with baclofen or benzodiazepines. Numerous medications have been used in the management of self-injurious behavior without much success.

lissencephaly syndrome (e.g., Miller-Dieker syndrome) *Disease category:* Malformation. *Clinical features:* Lissencephaly (LIS) and subcortical band heterotopia (SBH) comprise a spectrum of malformations of cortical development caused by insufficient neuronal migration. Main features of LIS include an abnormally thick cortex and reduced or absent formation of cerebral convolutions (“smooth brain”). SBH consists of abnormal bands of neurons beneath a normal cortex. Some patients with LIS have severe congenital microcephaly, referred to as microlissencephaly. *Associated complications:* Intellectual disability, seizures, dysmorphic features, late tooth eruption, poor weight gain, dysphagia (swallowing difficulty), congenital heart defect, and intestinal atresia (congenital closure). Those with multiple congenital anomalies in addition to LIS fall under the Miller-Dieker and Baraitser-Winter cerebrofrontofacial syndromes and X-linked LIS with abnormal genitalia. *Cause:* 19 genes have been defined to date that cause lissencephaly, the most common being *PAFAH1B1* (previously *LIS1*) and *DCX*. *Inheritance:* NM with AD inheritance when passed from an affected individual or XLR (males are typically more severely affected while females have a milder phenotype); possibly increased recurrence risk if one parent has a balanced chromosomal translocation of chromosome 17p. *Prevalence:* Rare.

Lowe syndrome (oculocerebrorenal syndrome) *Disease category:* Multiple congenital anomalies. *Clinical features:* Bilateral cataracts at birth, hypotonia, absent deep tendon reflexes, kidney dysfunction (proximal renal tubular dysfunction), and dysmorphic facies. *Associated complications:* Poor weight gain, short stature, vitamin D-resistant rickets, seizures, visual

impairment (corrected acuity is usually 20/100), glaucoma, intellectual disability in 75%, behavioral problems, intention tremor, craniosynostosis, and peripheral neuropathy (damage to nerves). Female carriers have characteristic findings in the lens (opacities) of each eye. *Cause:* Abnormal inositol phosphate metabolism caused by mutations in *OCRL1* (Xq26.1). *Inheritance:* XLR, with one third of cases being NM. *Prevalence:* 1:100,000.

mandibulofacial dysostosis *See* Treacher Collins syndrome.

maple syrup urine disease (MSUD) *Disease category:* Inborn error of metabolism: amino acid. *Clinical features:* A disorder of branched chain amino acid metabolism with four identified clinical variants (classic, intermittent, intermediate, and thiamine-responsive); the classic form comprises 75% of cases and is characterized by a maple syrup odor in the cerumen (ear wax) and urine from birth to 7 days of age, severe opisthotonos (spasm with body in a bowed position and head and heels bent backward), hypertonia, hypoglycemia, lethargy, and respiratory difficulties. Symptoms appear within the first 48 hours of life; if untreated, it is most often fatal within 1 month. Untreated survivors have severe intellectual disability and spasticity. The intermittent form presents with periods of ataxia, behavior disturbances, drowsiness, and seizures. Attacks are triggered by infections, excessive protein intake, or other physiological stresses. Individuals with the intermediate form usually demonstrate mild to moderate intellectual disability. *Associated complications:* Acidosis, hypoglycemia, growth retardation, and feeding problems; acute episodes are characterized by muscle fatigue, vomiting, impaired cognitive ability, hyperactivity, sleep disturbance, hallucinations, dystonia, and ataxia. *Cause:* Deficiency in branched-chain alpha keto-acid dehydrogenase caused by mutations in *BCKDHA* (1p31), *BCKDHB* (6p22), and *DBT* (19q13.1). *Prevalence:* 1:185,000; increased prevalence in the Mennonite population, with an incidence of 1:380. *Inheritance:* AR. *Treatment:* High-calorie diet with restriction of leucine and supplementation with isoleucine and valine. If instituted early (within 2 weeks of birth), the prognosis is

good for typical intelligence. Thiamine is used in the thiamine-responsive form. Orthotopic liver transplantation is effective for classic MSUD.

Marfan syndrome *Disease category:* Connective tissue disorder. *Clinical features:* Tall, thin body; upward dislocation of ocular lens; myopia; spiderlike limbs; and hypermobile joints. Average intelligence is expected, although learning disabilities have been reported in up to 50% of children. *Associated complications:* Aortic dilatation or dissection, congestive heart failure, mitral valve prolapse, emphysema, sleep apnea, pectus excavatum (sunken breastbone), or pectus carinatum (pigeon breastbone), and scoliosis. *Cause:* Mutation in *FBN1* (15q15–q21.3). *Inheritance:* AD with wide clinical variability. *Prevalence:* Estimated to be about 1:5,000. *Treatment:* Use of Losartan, an angiotensin II type 1 receptor blocker has been shown to prevent aortic aneurysm through the inhibition of transforming growth factor beta in mice. Doxycycline has also been shown to normalize aortic vasomotor function and suppress aneurysm growth. Trials continue with both of these medications.

Maroteaux-Lamy syndrome (MPS VI) *See* mucopolysaccharidoses.

McCune-Albright syndrome (polyostotic fibrous dysplasia) *Disease category:* Endocrine disorder. *Clinical features:* Large café-au-lait spots with irregular borders; fibrous dysplasia of bones (thinning of the bone with replacement of bone marrow with fibrous tissue, producing pain and increasing deformity), bowing of long bones, and premature onset of puberty; advanced bone age. *Associated complications:*

Hearing or visual impairment, hyperthyroidism, hyperparathyroidism (increased activity of the parathyroid gland, which controls calcium metabolism), abnormal adrenal function, increased risk of malignancy, and occasional spinal cord anomalies. *Cause:* Postmitotic mutation in the *GNAS1* (20q13) causing a defect in the enzyme adenyl cyclase. *Inheritance:* NM arising after fertilization (somatic mosaic) will be passed in an AD fashion if reproductive organs are involved; theoretically lethal unless present in the mosaic form. *Testing:* Mutations in the *GNAS1* gene were found to only be present in 46% of patients presenting with the classic triad. Other tissue types may need to be tested to confirm the presence of the common mutation. *Prevalence:* Rare. Estimates between 1:100,000–1:1,000,000.

MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) *See* mitochondrial disorders.

Menkes syndrome (kinky hair syndrome) *Disease category:* Inborn error of metabolism: copper. *Clinical features:* An inborn error of copper metabolism presenting at age 2–3 months with neurologic changes, “steely” texture of hair, and characteristic face with pudgy cheeks. *Associated complications:* Seizures, feeding difficulties, hypotonia, severe intellectual disability, recurrent infections, visual loss, bony abnormalities with tendency toward easy fracture, thrombosis, and early death. *Cause:* Copper deficiency from decreased absorption and/or missing enzymes caused by mutations in the adenosine triphosphatase *ATP7A* gene at Xq13. *Inheritance:* XLR, although some females may present with variable symptoms. *Prevalence:* 1:100,000. *Treatment:* Treatment with copper-histidine has been found to prevent neurological deterioration when provided before the age of 2 months. Treatment provided after 2 months of age cannot prevent neurologic, connective tissue, or bone complications.

MERRF (myoclonic epilepsy with ragged red fibers)
See mitochondrial disorders.

metachromatic leukodystrophy (arylsulfatase A deficiency) *Disease category:* Inborn error of metabolism: lysosomal storage disorder. *Clinical features:* Metachromatic leukodystrophy (MLD) is split into three subtypes based on age of onset: late-infantile, juvenile, and adult. The enzyme deficiency results in accumulation of toxins and leads to varying degrees of progressive neurological impairment, ranging from unsteady gait to severe rigidity and choreoathetosis. Muscle weakness, hypotonia, frequent falls, and ataxia are common. Onset of the infantile form is by 2 years of age and usually results in death by age 5 (50%–60% of cases). The juvenile form generally begins between 3–16 years of age, is rarer (20%–30% of cases), and progresses more slowly. The adult form presents after age 16. *Associated complications:* Seizures, abdominal distension, and cognitive deterioration. *Cause:* Mutations in the arylsulfatase A (ARSA) gene (22q13.33) cause ASA enzyme deficiency and result in the accumulation of sphingolipid sulfatide. *Inheritance:* AR. *Prevalence:* 1:40,000–1:160,000. *Treatment:* Bone marrow transplantation may have beneficial effects on some tissues types but does not affect lipid storage in the brain. Best results when performed in presymptomatic and very early symptomatic patients with juvenile or adult forms of the disease.

References: Eichler, F. S., Cox, T. M., Crombez, E., Dali, C. I., & Kohlschütter, A. (2016). Metachromatic leukodystrophy: An assessment of disease burden. *Journal of Child Neurology*, 31(13), 1457–1463.

methylmalonic aciduria *Disease category:* Inborn error of metabolism: organic acidemia. *Clinical features:* An organic acidemia with multiple subtypes. In the infantile/non-B₁₂-responsive phenotype (most common form), infants are normal at birth but then develop lethargy, vomiting, dehydration, hepatomegaly, hypotonia, and encephalopathy. There is a rarer intermediate B₁₂-responsive type, which presents in the first few months to years with anorexia, poor weight gain, hypotonia, and developmental

delay. The atypical/benign adult subtype is associated with increased urinary excretion of methylmalonic acid but may remain asymptomatic. *Associated complications:* Variable developmental delay, kidney failure, metabolic stroke affecting the basal ganglia, movement disorder with choreoathetosis, dystonia, para/quadruparesis, pancreatitis, growth failure, immune dysfunction, and optic nerve atrophy. *Cause:* Isolated methylmalonic aciduria is found in patients with mutations in the MUT gene (6p21), causing partial, mut(-), or complete, mut(0), enzyme deficiency. This form is unresponsive to B₁₂ therapy. Various forms of isolated methylmalonic aciduria also occur in a subset of patients with defects in the synthesis of the MUT coenzyme adenosylcobalamin (AdoCbl) and are classified according to complementation group: cblA, caused by mutation in MMAA (4q31.1-q31.2), and cblB, caused by mutation in MMAB (12q24). Combined methylmalonic aciduria and homocystinuria may be seen in complementation groups cblC, cblD, and cblF. *Inheritance:* AR. *Prevalence:* 1:50,000–1:100,000. *Treatment:* Treatment consists of a low-protein, high-calorie diet and supplemental hydroxocobalamin (B₁₂) injections in those who have a B₁₂-responsive form; carnitine is also given. Liver and liver/kidney transplant have been performed to avoid continued damage to the kidneys, and some success has been reported. Carglumic acid has also been used to lower ammonia with good success.

Miller-Dieker syndrome See lissencephaly syndromes.

mitochondrial disorders (mitochondrial encephalopathies and myopathies) *Disease category:* Inborn error of metabolism/mitochondrial disorders. *Clinical features:* This diverse group of disorders is linked by a common etiology—abnormal function of the mitochondria (energy-producing intracellular structures) or abnormalities in mitochondrial metabolism. Mitochondrial disorders can affect every organ system. Common features include ptosis (droopy eyelids), external ophthalmoplegia (paralysis of the external eye muscles), myopathy, cardiomyopathy, short stature, and hypoparathyroidism. *Associated*

complications: Seizures, sensorineural hearing loss, optic atrophy, retinitis pigmentosa (pigmentary changes in retina causing loss of peripheral vision and clumping of pigment), cataracts, diabetes, migraine, intestinal pseudo-obstruction, reflux, kidney problems, and exercise intolerance. *Cause:* Genes encoding nuclear DNA and mitochondrial DNA (mtDNA) are known to cause mitochondrial disorders. Mutations in different genes may cause the same symptoms. *Inheritance:* AR, AD, NM, or may be inherited from the mother through mtDNA. *Prevalence:* 1:8,500 for all mitochondrial disorders combined. *Treatment:* Early diagnosis and treatment of diabetes, eye abnormalities, and cardiac disease. Coenzyme Q10 and riboflavin have been used with some reported benefit. Intravenous arginine has shown promise to those with stroke. Six mitochondrial disorders are discussed next.

Ganetzky, R. D., & Falk, M. J. (2018). 8-year retrospective analysis of intravenous arginine therapy for acute metabolic strokes in pediatric mitochondrial disease. *Molecular Genetics and Metabolism*, 123(3), 301–308.

Kearns-Sayre syndrome *Clinical features:* Short stature, progressive external ophthalmoplegia, retinitis pigmentosa, heart block, and cerebellar ataxia. Onset is usually in childhood, before age 20 years, with ptosis, ophthalmoplegia, or both. *Associated complications:* Visual impairment, bilateral hearing loss, myopathy, endocrine abnormalities, diabetes mellitus, hypoparathyroidism, dysphagia, and dementia. *Cause:* Deletions in mtDNA (90% have a 2–10 kb mtDNA deletion). *Inheritance:* Maternal, through mtDNA. *Prevalence:* 1:2:100,000 for large-scale mtDNA deletions. *Treatment:* Generally supportive, symptomatic treatment such as cochlear implant for hearing loss, cardiac pacemaker placement for those with cardiac conduction block, eyelid slings for severe ptosis, and hormone replacement for endocrinopathies. Folinic acid supplementation is suggested for those with low CSF folic acid, although recent papers note a lack of clinical response. Co-enzyme Q10 and L-carnitine are also often used.

Kearns-Sayre syndrome: A case series of

35 adults and children. *International Journal of Genetics Medicine*, 7, 325–332.

Leber hereditary optic neuropathy (LHON) *Clinical features:* Bilateral central vision loss beginning in young adulthood. Patients usually become legally blind. *Associated complications:* Occasionally seen with multiple sclerosis (usually in women); peripheral neuropathy and movement disorders have all been reported as more common in individuals with LHON. *Cause:* Primarily associated with point mutations in mtDNA. *Inheritance:* Maternal, through mtDNA. Males are four to five times more likely to be affected. *Prevalence:* 1:31,000–1:50,000. *Treatment:* Current treatment is typically supportive with visual aids, occupational rehabilitation, and treatment for raised intraocular pressure for those who have that complication. Gene therapy with AAV2 for those with point mutation G11778A in *MT-ND4* is currently being investigated with good safety data in a Phase 1/2 trial.

Leigh syndrome (subacute necrotizing encephalomyopathy) *Clinical features:* Encephalopathy, ophthalmoplegia, optic atrophy, and myopathy. *Associated complications:* Developmental delay and regression, ataxia, spasticity, hypertrophic cardiomyopathy, and early death. Onset usually between 3–12 months of age, often after a viral infection. *Cause:* Mutations in many different nuclear and mitochondrial genes involved in energy metabolism, including respiratory chain complexes I, II, III, IV, and V, as well as tRNA proteins, and pyruvate dehydrogenase complex. *Inheritance:* Maternal, AR, XLR. *Prevalence:* 1:30,000–1:40,000. *Treatment:* Usually includes sodium bicarbonate or sodium citrate for acute exacerbations of lactic acidosis and antiepileptic drugs for seizures. Medications for dystonia include benzhexol, baclofen, tetrabenazine, or gabapentin. Anticongestive therapy may be required for cardiomyopathy. Anecdotal reports suggested that dichloroacetate (DCA) may have had short-term clinical improvement, but a double-blind, placebo-controlled trial in MELAS showed a toxic effect of DCA on peripheral nerves. A vitamin cocktail is

often given that includes riboflavin, thiamine, and coenzyme Q10. A ketogenic diet may be used in those with refractory epilepsy.

MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) *Clinical features:* Migraine headaches, seizures, stroke-like episodes, encephalopathy (degenerative disease of the brain), and myopathy. *Associated complications:* Progressive hearing loss, cortical blindness, ataxia, dementia, lactic acidosis, recurrent vomiting, and hemiparesis. *Cause:* A mutation in mtDNA encoding transfer RNA causes reduced mitochondrial protein synthesis. *Inheritance:* Maternal, through mtDNA. *Treatment:* IV arginine therapy has shown significant therapeutic benefit in pediatric mitochondrial disease stroke subjects in those with MELAS, as well as other diagnoses. Acute hemiplegic stroke was particularly responsive to IV arginine treatment.

MERRF (myoclonic epilepsy with ragged red fibers) *Clinical features:* Myoclonic epilepsy, ataxia, spasticity, and myopathy. *Associated complications:* Optic atrophy, sensorineural hearing loss, peripheral neuropathy, diabetes, cardiomyopathy, dementia, and lipomas (fatty tumors); characteristic ragged red muscle fibers are seen on muscle biopsy examination. *Cause:* Mutations in mtDNA encoding transfer RNA. *Inheritance:* Maternal, through mtDNA. *Treatment:* Conventional antiepileptic drugs for seizures, physical therapy for impaired motor function, and standard pharmacologic therapy for cardiac symptoms. Typically levetiracetam, clonazepam, zonisamide, and valproic acid have been used for myoclonic epilepsy. Valproate can cause secondary carnitine

deficiency, however, and should be avoided or used with L-carnitine supplementation. Coenzyme Q10 and L-carnitine are often given with the idea that they may improve mitochondrial function. Aerobic exercise is thought to be helpful.

NARP (neuropathy, ataxia, retinitis pigmentosa) *Clinical features:* Proximal neurogenic muscle weakness with sensory neuropathy, ataxia, and pigmentary retinopathy. *Associated complications:* Seizures, learning difficulties, dementia, short stature, sensorineural hearing loss, progressive external ophthalmoplegia, and cardiac conduction defects. Often stable, but can have episodic deterioration with viral illness. *Cause:* Mutation in the ATP synthase 6 gene. *Inheritance:* Maternal, through mtDNA. *Treatment:* Similar to Leigh syndrome.

References: Claeys, K. G., Abicht, A., Hausler, M., Kleinle, S., Wiesmann, M., Schulz, J. B., . . . Weis, J. (2016). Novel genetic and neuropathological insights in neurogenic muscle weakness, ataxia, and retinitis pigmentosa (NARP). *Muscle and Nerve*, 54(2), 328–333.

Rawle, M. J., & Larner, A. J. (2013). NARP syndrome: A 20-year follow-up. *Case Reports in Neurology*, 5(3), 204–207.

Moebius sequence/syndrome (congenital facial diplegia) *Disease category:* Multiple congenital anomalies. *Clinical features:* Facial paralysis resulting in an expressionless face and facial weakness (bilateral in 92% of cases and unilateral in 8%) due to palsies of the 6th, 7th, and occasionally 12th cranial nerves; occasional abnormalities of fingers and legs; micrognathia; eye abnormalities, including esotropia (“cross-eyed”), and vision problems, including myopia, astigmatism, and amblyopia (impaired vision); and craniofacial malformations. *Associated complications:* Feeding difficulties, oral motor dysfunction, articulation disorder, occasional tracheal or laryngeal anomalies, gross and fine motor delay and dysfunction, and learning disabilities. *Cause:* Linked to 13q12.2-q13 but no known gene. *Inheritance:* Not well characterized; most reported cases are SP, possibly due to an NM; rare reports of AD cases with variable expressivity. *Prevalence:* 1:50,000.

monosomy X See Turner syndrome.

Morquio syndrome (MPS IV) See mucopolysaccharidoses.

MSUD See maple syrup urine disease.

mucopolysaccharidoses (MPS) *Disease category:* Inborn error of metabolism: lysosomal storage disorder. *Clinical features:* Glycosaminoglycans accumulate within the lysosomes in these seven distinguishable forms of the disorder, each with two or more subgroups. Features shared by most include coarse facial features, thick skin, hirsutism (excessive hair), corneal clouding, and organomegaly (enlargement of spleen and liver). Growth deficiency, intellectual disability, cardiomyopathy, and skeletal dysplasia are also seen. Intelligence is normal in MPS type IV (Morquio syndrome) and MPS type VI (Marataux-Lamy). The various MPS disorders are differentiated by their clinical features, enzymatic defects, genetic transmission, and urinary mucopolysaccharide pattern. *Inheritance:* All are AR except MPSII (Hunter syndrome), which is XLR. *Prevalence:* Overall estimated to be 1:22,500. MPS I (Hurler, Scheie, and Hurler-Scheie syndromes), MPS II (Hunter syndromes), and MPS III (Sanfilippo syndrome) are discussed next. Others include MPS IV (Morquio syndrome), MPS VI (Maroteaux-Lamy syndrome), and MPS VII (Sly syndrome).

MPS I (Hurler syndrome, Scheie syndrome, and Hurler-Scheie syndrome) Previously known as Hurler and Scheie syndrome, these disorders are now denoted as severe MPS I or attenuated MPS I. *Clinical*

features: Patients with the severe MPS I are normal at birth, but then gradual coarsening of facial features in early childhood becomes apparent. They also have hypertrichosis (excessive hair), a large skull, organomegaly, prominent lips, corneal clouding, dysostosis (malformed bones), and stiffening of joints. There is progressive intellectual deterioration and spasticity by age 3, and growth typically stops. Death typically occurs by age 10. The attenuated form is characterized by hearing loss, cardiac valvular disease, progressive restriction in range of motion with typical stature, typical intelligence (although some may have learning disabilities), and survival into adulthood. *Associated complications:* Chronic ear infections, hearing loss, occasional hernia, visual impairment, brain cysts, and airway obstruction. *Cause:* Deficiency of enzyme alpha-L-iduronidase caused by mutations in *IDUA* (4p16.3). *Inheritance:* AR. *Incidence:* 1:100,000 for the severe form and 1:500,000 for the attenuated form. *Treatment:* Hematopoietic stem cell transplantation (HSCT) in severe MPS I patients can increase survival, improve facial coarseness and hepatosplenomegaly, improve hearing, and maintain normal heart function (but does not improve skeletal manifestations or corneal clouding). HSCT may slow the course of cognitive decline in those with mild impairment at the time of transplant. Enzyme replacement therapy with Aldurazyme is licensed for treatment of non-CNS manifestations of MPS I and improves liver size, growth, joint mobility, breathing, and sleep apnea in those with attenuated disease.

MPS II (Hunter syndrome) *Clinical features:* Features include short stature; enlarged liver and spleen; coarsening of facial features, with hypertrichosis beginning in early childhood; and hoarse voice. Intellectual disability is mild or absent in the attenuated form of the disease; this subtype is compatible with survival to adulthood. The severe form is highlighted by progressive intellectual deterioration first noted between 2–3 years of age; death occurs before age 15 in most cases and is similar to severe MPS I but with clear corneas. *Associated complications:* Sensorineural hearing loss; retinitis pigmentosa with visual loss; macrocephaly; stiffening of joints, particularly those in the hands; cardiac valve disease; hernia; respiratory insufficiency; chronic diarrhea; and seizures. *Cause:* Deficiency of enzyme iduronate-2-sulfatase caused by mutations in *IDS* (Xq28). *Inheritance:* XLR. *Incidence:* 1:100,000–1:170,000 male births. *Treatment:* Minimal success has been reported with bone marrow transplantation. Enzyme replacement therapy for MPS II is now available (idursulfase/Elaprase). Elaprase does not cross the blood-brain barrier,

and thus it is not expected that there would be any effect on CNS disease, although early treatment does improve somatic manifestations.

MPS III (Sanfilippo syndrome) *Clinical features:* Four distinct types representing four different enzyme defects with similar clinical features; clinical features present between 2–6 years in children who otherwise appear typical. There is mild coarsening of facial features, coarse hair and hirsutism, absence of corneal clouding, mild enlargement of the liver, joint stiffness, sleep disorders, and progressive mental deterioration. Deterioration is most rapid in type IIIA; death occurs by 10–20 years in most cases. *Associated complications:* Severe behavioral disturbances by age 4–6 years, dysostosis (defective bone formation), diarrhea in 50%, progressive spasticity and ataxia, precocious puberty, and central breathing are problems with advancing disease. *Cause:* Type IIIA: Deficiency of enzyme heparan sulfatase caused by mutations in *SGSH* (17q25.3). Type IIIB: Deficiency of enzyme alpha-N-acetylglucosaminidase caused by mutations in *NAGLU* (17q21). Type IIIC: Deficiency of enzyme acetyl-CoA: alpha-glucosaminide N-acetyltransferase caused by mutations in *HGSNAT* (8p11.2-p11.1). Type IIID: Deficiency of enzyme N-acetyl-alpha-glucosaminine-6-sulfatase caused by mutations in *GNS* (12q14). *Inheritance:* AR. *Incidence:* 1:73,000–1:280,000. *Treatment:* Treatment is supportive only. Bone marrow transplantation has not been successful.

multiple acyl-CoA dehydrogenase deficiency *See* glutaric acidemia, type II.

muscular dystrophy, Duchenne (DMD) and Becker (BMD) types *Disease category:* Neuromuscular disease. *Clinical features:* Progressive proximal muscular degeneration, muscle wasting, hypertrophy (enlargement) of calves, and cardiomyopathy; onset of symptoms in DMD occurs before 3 years. Loss of ability to walk independently occurs by adolescence in DMD. The onset in BMD is later, and the progression is slower. *Associated complications:* Congestive heart failure, scoliosis, flexion contractures, respiratory compromise, and intestinal motility dysfunction (causing constipation); approximately one third of boys with DMD have learning or intellectual disabilities. *Cause:* Mutations in *DMD* (Xp21.1), which encodes dystrophin. *Inheritance:* XLR, with one third of cases due to an NM. *Incidence:* DMD 1:3,500 male births; BMD 1:20,000 males. There are reports of females with clinical features of DMD as the result of X-chromosome rearrangements involving the *DMD* locus because they have Turner syndrome (i.e., complete or partial absence of an X chromosome) or

nonrandom X-chromosome inactivation. *Treatment:* Glucocorticosteroids have been shown to prolong ambulation; prednisone and deflazacort have been shown to improve strength and function. In September 2016, the FDA approved eteplirsen (EXONDYS 51) a phosphorodiamidate morpholino oligomer (PMO) drug that acts to promote dystrophin protein production by restoring the translational reading frame of DMD through specific skipping of exon 51 in defective gene variants. While studies have showed an increase in dystrophin production, more data are needed to show clinical benefit. *See also* Chapter 9.

myasthenia gravis *Disease category:* Neuromuscular disease. *Clinical features:* Proximal muscle weakness, facial muscle weakness, difficulty chewing, ptosis, dysarthria, dysphagia, and ventilatory insufficiency. *Cause:* Failure of chemical transmission at the neuromuscular junction. It is an autoimmune disorder in which antibodies interfere with neuromuscular transmission. Although in rare instances genetic in origin, it is most often acquired as an autoimmune disorder. *Incidence:* 1:30,000. *Treatment:* Treatment is directed at removing the offending antibody and increasing the level of acetylcholine in the synaptic cleft. The immunological approach has employed corticosteroid medication, immunoglobulin, plasmapheresis, and the surgical removal of the thymus gland. Transient symptom improvement due to increased neurotransmitter levels in the synaptic cleft is achieved with pyridostigmine (Mestinon). Using these various treatment approaches, individuals with myasthenia can lead quite typical lives.

myotonic dystrophy (Steinert disease) *Disease category:* Neuromuscular disease. *Clinical features:* The most prominent feature is myotonia, a form of dystonia involving increased muscular contractility combined with decreased power to release (e.g., a strong handshake with the inability to release it). Other features include myopathy (muscle weakness), dysarthria, ptosis (drooping eyelids), and frontal balding. The age of onset varies from childhood to adulthood. The congenital form is severe, with neonatal hypotonia, motor delay, intellectual disability, and facial muscle palsy. In the congenital form, feeding difficulties and severe respiratory problems are common. In classic myotonia, symptoms do not begin until around 10 years of age. *Associated complications:* Cataracts, cardiac conduction abnormalities, diabetes, and hypogonadism (reduced hormone secretion in testes/ovaries). *Cause:* Type 1 myotonic dystrophy (DM1) is caused by cytosine-thymine-guanine (CTG) expansion mutations in *DMPK* (19q13). Severity typically increases with the number of CTG repeats. Unaffected people have 5–30 repeat copies. Those with the classical adult form have more than 100 copies, and individuals with the congenital form usually have more than 1,000 copies. The correlation among the number of repeats, severity, and age of onset, however, is not always consistent. Myotonic dystrophy type 2 (DM2) is associated with CCTG repeat expansion in *CNBP* (*ZNF9*) (3q13.3-q24). Normal alleles have up to 30 repeats; those affected have 75–11,000 repeats, with an average of 5,000. *Inheritance:* AD with genetic anticipation (repeat expands in subsequent generations and the onset of symptoms becomes earlier); with rare exception, it is the mother who transmits mutations that expand enough to cause the congenital form. There have been no reported *de novo* mutations in DM2. *Prevalence:* 1:8,000; increased prevalence in certain areas of Quebec.

Nager syndrome *See* acrofacial dysostosis.

neonatal adrenoleukodystrophy *See* adrenoleukodystrophy, neonatal form.

neurofibromatosis, type I (NF1) *Disease category:* Neurological disorder. *Clinical features:* Multiple café-au-lait spots, axillary (armpit) and inguinal (groin) freckling, nerve tumors (fibromas) in body and on skin, and Lisch nodules (brown bumps on the iris of the eye). *Associated complications:* Glaucoma, scoliosis, hypertension, attention-deficit/hyperactivity disorder (ADHD), macrocephaly (enlarged head) or hydrocephalus, visual impairments (secondary to optic gliomas), and increased risk of numerous malignant and benign tumors in the nervous system (malignant peripheral nerve sheath tumors in 8%–13% of patients); verbal and nonverbal learning disabilities occur in 30%–65% of patients. *Cause:* Mutation in *NF1* (17q11.2), which codes for neurofibromin protein. *Inheritance:* AD with variable expression. Approximately 50% represent NM. *Prevalence:* 1:3,000.

References: Eijk, S., Mous, S. E., Dieleman, G. C., Dierckx, B., Rietman, A. B., deNijs, P. F. A., . . . Legerstee, J. S. (2018). Autism spectrum disorder in an unselected cohort of children with neurofibromatosis type 1 (NF1). *Journal of Autism and Developmental Disorders*, 48(7), 2278–2285.

neurofibromatosis, type II *Disease category:* Neurological disorder. *Clinical features:* Bilateral vestibular schwannomas (benign tumors of auditory nerve), cranial and spinal tumors, neuropathy, and café-au-lait spots (usually fewer than six); in contrast to type I, no Lisch nodules or axillary freckling are seen. *Associated complications:* Deafness (average age of onset is 20 years), cataracts or other ocular abnormalities, and meningiomas (benign tumor of the meninges); tumor growth rates are variable within the same patients and between patients. *Cause:* Mutation in the tumor-suppressor gene (*NF2*) encoding the merlin protein (22q12.2); genotype/phenotype studies show that nonsense mutations (mutations that create a stop codon) are associated with more severe disease presentation than other types of genetic mutations. *Inheritance:* AD with significant variability between patients; up to 50% may represent NM. *Prevalence:* 1:60,000. *Treatment:* Mortality is lower for patients treated in specialty centers. Microsurgery and radiation therapy are both commonly used. Sirolimus is also in clinical trials for treatment of progressive neurofibromatosis type I-associated plexiform neurofibromas.

neuronal ceroid lipofuscinosis, juvenile See Batten disease.

Niemann-Pick disease, types A and B (acid sphingomyelinase deficiency) *Disease category:* Inborn error of metabolism: lysosomal storage disorder. *Clinical features:* Acid sphingomyelinase deficiency. Type A is neuronopathic and presents in infancy with poor weight gain, enlarged liver and spleen, and rapidly progressive neurological decline. Death occurs by age 2–3 years. Type B is nonneuronopathic and variable but compatible with survival to adulthood and may cause few or no neurological abnormalities. *Associated complications:* Intellectual disability, ataxia, myoclonus, eye abnormalities, coronary artery disease, and lung disease. Main clinical features of type B are enlargement of the spleen and liver resulting in liver dysfunction, as well as cardiac disease, lipid abnormalities, pulmonary involvement, and growth retardation. *Cause:* Sphingomyelinase enzyme deficiency caused by mutations in *SMPD1* (11p15.4). *Inheritance:* AR. *Prevalence:* 1:250,000; incidence of type A is increased in the Ashkenazi Jewish population, and type B is seen equally in all ethnic groups. *Treatment:* Enzyme replacement therapy (olipudase alfa) is being studied with promising improvement of clinical measures and good tolerability.

Noonan syndrome *Disease category:* Multiple congenital anomalies. *Clinical features:* Short stature; characteristic facial features, including a triangular shape, deep philtrum (vertical indentation in the middle area of the upper lip), down-slanting palpebral fissures (opening between the eyelids), ptosis, low-set

ears, and a low posterior hairline; a short or webbed neck; congenital heart defects (usually pulmonary valve stenosis or hypertrophic cardiomyopathy); and a shield-shaped chest. One third of cases have mild intellectual disability. *Associated complications:* Sensorineural deafness, malocclusion of teeth, learning disabilities with deficits in verbal learning, attention-deficit/hyperactivity disorder, poor motor coordination, bleeding, and lymphatic abnormalities. *Cause:* Nine genes are linked to Noonan syndrome: *PTPN11* (12q24.13), *SOS1* (2p22.12), *RAF1* (3p25.2), *KRAS* (12p12.1), *NRAS* (1p13.2), *RIT1* (1q22), *BRAF* (7q34), *SOS2* (14q21.3), and *LZTR1* (22Q11.21). *Inheritance:* AD, 25%–50% NM. Recent report of AR mutations in *LZTR1*. *Prevalence:* 1:1,000–1:2,500. *Treatment:* Human growth hormone has been used to treat short stature in some patients with Noonan syndrome.

oculo-auriculo-vertebral spectrum (facioauriculo-vertebral spectrum, Goldenhar syndrome, hemifacial microsomia) *Disease category:* Multiple congenital anomalies. *Clinical features:* Unilateral external ear deformity ranging from absence of an ear to microtia (tiny ear), preauricular (earlobe) tags or pits, middle-ear abnormality with variable hearing loss, facial asymmetry with a small size unilaterally, macrostomia (wide mouth), occasional cleft palate, and microphthalmia (abnormally small eyes), or eyelid coloboma. *Associated complications:* Vertebral anomalies, occasional heart and kidney defects, and intellectual disability in 10%. *Cause:* Unknown. Recent array-CGH studies on a cohort of patients were unable to identify a recurrent chromosomal abnormality. *Inheritance:* Genetically heterogeneous; may be SP in some cases resulting from gestational maternal diabetes; cases with clear AR and AD inheritance have been reported. *Prevalence:* 1:45,000 in Northern Ireland, presumably less common in other populations. *Incidence:* 1:3,000–1:25,000.

oculo-mandibulo-dyscephaly with hypotrichosis See Hallermann-Streiff syndrome.

Opitz GBB syndrome (Opitz-Frias syndrome and Opitz oculo-genito-laryngeal syndrome; previously separate and called G syndrome and BBB syndrome [G refers to the surname of the original patient described]) *Disease category:* Multiple congenital anomalies. *Clinical features:* Hypertelorism (widely spaced eyes), hypospadias (opening of the urethra on the underside of the penis), imperforate (without an opening) anus, dysphagia, bifurcated (divided) nasal tip, broad nasal bridge, widow's peak, occasional cleft lip/palate, and mild to moderate intellectual disability in two thirds of affected individuals. *Associated complications:* Gastroesophageal reflux; esophageal dysmotility (poor movement of food through the esophagus); hoarse cry; occasional congenital heart defect; agenesis (absence) of corpus callosum; platelet abnormalities; and structural cerebellar anomalies, including Dandy-Walker malformation. *Cause:* Mutation in *MID1* (Xp22.3) is known to cause the X-linked form. Mutation in *SPECC1L* (22q11.23) causes the AD form. Deletion of 22q11.2 has also been linked and may result in 22q11 deletion syndrome as well. *Inheritance:* AD and XLR; in both the AD and XLR forms, symptoms are more severe in males than in females. *Prevalence:* 1:50,000–1:100,000 in the X-linked form.

osteogenesis imperfecta (OI) *Disease category:* Connective tissue disorder. *Clinical features:* There are multiple types of OI. Type I is characterized by typical height or mild short stature, bone fragility, and

blue sclera. Type II usually presents with severe bone deformity and death in the newborn period. Type III is characterized by progressive bone deformity, short stature, triangular face, severe scoliosis, and dental abnormalities. Type IV is clinically similar to type I but presents with normal sclerae, milder bone deformity, variable short stature, and dental abnormalities. Type V is similar to type IV but with hyperplastic callus formation at fracture sites (excessive collection of partly calcified tissue, formed in the blood clot around the site of a healing fracture), calcification of the interosseous membrane between the radius and ulna (the fibrous joint between the two bones of the forearm), and the presence of a radiopaque metaphyseal band adjacent to the growth plates (zone of increased bone density found at the ends of long bones). Type VI is characterized by severe bone deformity, with a moderate short stature and a fish-scale pattern of bone deposition. Type VII causes moderate bone deformations and a mild short stature, with a shortening of the long bones (humerus and femur). *Associated complications:* Increased prevalence of fractures (may be confused with physical abuse) that decreases after puberty, scoliosis, mitral valve prolapse, and occasionally progressive adolescent-onset hearing loss. *Cause:* There are now 19 different genes associated with OI. Mutations in *COL1A1* (17q21-22) and *COL1A2* (7q21-22) represent 80% of OI cases. The other genes include *IFITM5*, *SERPINF1*, *CRTAP*, *LEPRE1*, *PP1B*, *SERPINH1*, *FKBP10*, *PLOD2*, *BMP1*, *SP7*, *TMEM38B*, *WNT1*, *CREB3L1*, *SPARC*, and *MBTPS2*. *Inheritance:* AD, AR, XLR. *Prevalence:* 1:30,000. *Treatment:* Cyclic intravenous pamidronate therapy to increase bone mineral density. See Chapter 9.

pentasomy X See XXXXX syndrome.

Pfeiffer syndrome (acrocephalosyndactyly, type V) *Disease category:* Craniosynostosis. Three subtypes of Pfeiffer syndrome have been described with a range of clinical severity. *Clinical features:* Mild craniosynostosis (premature fusion of fibrous sutures on the skull) with brachycephaly (flat head), flat midface,

broad thumbs and toes, hypertelorism (widely spaced eyes), and partial syndactyly (fusion of digits). *Associated complications*: Hydrocephalus, airway obstruction due to midface hypoplasia (underdevelopment), hearing impairment, seizures, and occasional intellectual disability. *Cause*: Mutations in *FGFR1* and *FGFR2* (8p11.2–p11.1 and 10q26). *Inheritance*: AD, with many cases due to NM. *Prevalence*: 1:100,000.

References: Giancotti, A, D'Ambrosio, V., Marchionni, E., Squarcella, A., Aliberti, C., La Torre, R., . . . PECRAM Study Group. (2017). Pfeiffer syndrome: literature review of prenatal sonographic findings and genetic diagnosis. *Journal of Maternal Fetal Neonatal Medicine*, 30, 2225–2231.

phenylketonuria (PKU) *Disease category*: Inborn error of metabolism: amino acid. *Clinical features*: Inborn error of amino acid metabolism without acute clinical symptoms; intellectual disability, microcephaly, abnormal gait, and seizures may develop in untreated individuals. Treated individuals have still been found to have mild cognitive deficits, especially in executive function. Pale skin and blond hair are common features. *Associated complications*: Behavioral disturbances, cataracts, skin disorders, and movement disorders. *Cause*: Classically caused by a deficiency of the enzyme phenylalanine hydroxylase, which is associated with a mutation in *PAH* (12q24.1). *Inheritance*: AR. *Prevalence*: 1:10,000 among Caucasians in the United States. *Treatment*: Early identification is available through newborn screening. A phenylalanine-restricted, low-protein diet should be continued for life and especially in females during childbearing years. Returning to a regular diet even in adulthood may cause reduction of IQ. Specialized formulas are available for individuals who need to be on the restricted diet. Sapropterin dihydrochloride (Kuvan), a synthetic formulation of the cofactor tetrahydrobiopterin (BH4) is approved to reduce blood phenylalanine levels in patients with hyperphenylalaninemia due to tetrahydrobiopterin-responsive PKU. *See also* Chapter 16.

phenytoin syndrome (fetal hydantoin syndrome) *Disease category*: Malformation. *Clinical features*: Intrauterine growth restriction with microcephaly and minor dysmorphic craniofacial features and limb defects, including hypoplastic nails and distal phalanges (underdeveloped nails and digits). *Associated complications*: Growth problems and developmental delay or intellectual disability. *Cause*: Maternal ingestion of phenytoin (Dilantin) during pregnancy. *Prevalence*: About one third of children whose mothers are taking this drug during pregnancy have features of phenytoin syndrome. *Treatment*: Surgical correction of cranial facial and limb defects when required and feasible.

Reference: Hegde, A., Kaur, A., Sood, A., Dhanorkar, M., Varma, H.T., Singh, G., . . . Kumar, P. (2017). Fetal hydantoin syndrome. *Journal of Pediatrics*, 188, 304.

Pierre-Robin sequence *Disease category*: Malformation. *Clinical features*: Micrognathia (undersized jaw), cleft palate, and glossoptosis (downward displacement of tongue). *Associated complications*: Neonatal feeding problems, apnea or respiratory distress, upper airway obstruction, and gastrointestinal reflux. *Cause*: Impaired closure of the posterior palatal shelves early in embryonic development; this defect can be an isolated finding or can be associated with trisomy 18, Stickler syndrome, or certain other syndromes. *Inheritance*: AR. *Prevalence*: Unknown. *Treatment*: Surgical procedure can be used to correct micrognathia, which alleviates many of the feeding and respiratory problems.

PKU *See* phenylketonuria.

polyostotic fibrous dysplasia *See* McCune-Albright syndrome.

Prader-Willi syndrome (PWS) *Disease category*: Multiple congenital anomalies/imprinting defect/contiguous gene. *Clinical features*: Short stature; poor weight gain in infancy; hyperphagia (abnormally increased appetite); almond-shaped eyes; viscous (thick) saliva; hypotonia, particularly in the neck region; hypogonadism with cryptorchidism; small hands and feet; and hypopigmentation. *Associated complications*: Mild to moderate intellectual disability,

behavior problems (tantrums, obsessive-compulsive disorder, rigidity, food stealing, and skin picking), obstructive sleep apnea, high pain threshold, osteoporosis, neonatal temperature instability, and type 2 diabetes. *Cause*: PWS is caused by a lack of expression of the paternally derived region of 15q11.2-q13. Approximately 65%–75% have a microdeletion, and 20%–30% have maternal uniparental disomy. Other mechanisms include unbalanced chromosome rearrangements and an imprinting defect with a deletion in the imprinting center. *Inheritance*: NM with AD inheritance when passed from an affected individual, although most individuals with PWS do not reproduce. *Prevalence*: 1:10,000–1:30,000. *Treatment*: Weight management and close supervision to minimize food stealing. No medications are currently able to control hyperphagia, but there are several clinical trials of new medications underway. Growth hormone treatment normalizes height.

propionic acidemia *Disease category*: Inborn error of metabolism: organic acidemia. *Clinical features*: A disorder of organic acid metabolism characterized by episodes of vomiting, lethargy, and coma; hypotonia, bone marrow suppression, enlarged liver, and characteristic facies with puffy cheeks and exaggerated Cupid's bow upper lip. *Associated complications*: Impaired antibody production, intellectual disability, seizures, abnormalities of muscle tone, lack of appetite, prolonged drowsiness, cardiomyopathy, optic atrophy, hearing loss, premature ovarian failure, autism, anxiety, acute psychosis, and hematologic abnormalities. *Cause*: Deficiency of the enzyme propionyl-CoA carboxylase (PCC) caused by mutations in *PCCA* (13q32) and *PCCB* (3q21–q22). *Inheritance*: AR. *Incidence*: Varies widely worldwide. Highest in Greenlandic Inuits (1:1000) and in certain Saudi tribes (1:2,000–1:5,000). In the United States, the live-birth incidence is 1:105,000–1:130,000. *Treatment*: Treatment consists of a diet low in valine, isoleucine,

threonine, and methionine, with a supplement of carnitine. A commercial formula meeting these requirements (Propimex) is available. Hemofiltration and peritoneal dialysis have been used with some success in patients in metabolic crisis. Some success has been documented in treating hyperammonemia (elevated plasma ammonia level) in propionic acidemia patients with N-carbamylglutamate (carglumic acid). Liver transplantation has been used in some cases and is considered an option for patients who continue to experience episodes of hyperammonemia despite maximal medical treatment.

retinitis pigmentosa *Disease category*: Ophthalmologic. *Clinical features*: A group of diseases associated with retinal degeneration, constricted visual fields, and progressive blindness; initial symptom is night blindness occurring in adolescence or adult life and loss of peripheral vision. *Associated complications*: May occur as an isolated condition or as part of over 30 syndromes (e.g., Usher syndrome, Bardet-Biedl Syndrome, and mitochondrial disorders). *Cause*: More than 80 different genes have been identified to date. *Inheritance*: AD in 30%–40% of cases, AR in 50%–60%, and XLR in 5%–15%. A genetic cause is yet to be identified in the remainder. A rare digenic form where individuals are heterozygous for mutations in two genes also exists. Recurrence risk depends on cause and family history. *Incidence*: 1:3,500–1:4,000 in the United States and Europe.

Rett syndrome (Rett's disorder) *Disease category*: Progressive neurologic disorder. *Clinical features*: Typical development until 6–9 months of age, followed by progressive encephalopathy. Features of autism, loss

of purposeful hand use (with characteristic wringing of hands), hyperventilation, ataxia, and spasticity. *Associated complications:* Postnatal onset of microcephaly and seizures. *Cause:* Mutations in *MECP2* (Xq28). Mutations in *CDKL5* (Xp22.13) have been found in individuals with what has been characterized as the early-onset seizure variant of Rett. Mutations in *FOXG1* (14q12) are associated with the congenital form. *Inheritance:* XLD with severe neonatal encephalopathy or lethality in males who have *MECP2*-related Rett. *Prevalence:* 1:10,000 among females.

Riley-Day syndrome See familial dysautonomia.

Robinow syndrome (fetal face syndrome) *Disease category:* Skeletal dysplasia. *Clinical features:* Slight to moderate short stature, short forearms, macrocephaly with frontal bossing (prominent central forehead); flat facial profile with apparent hypertelorism; small, upturned nose; hypogenitalism; micrognathia; small face; tented upper lip with occasional clefting of the lower lip; hypertrophy (overgrowth) of the gums; deficiency of the lower eyelid, giving the appearance of protruding eyes (exophthalmos); and congenital heart defects. *Associated complications:* Vertebral or rib anomalies, dental malocclusion, genital hypoplasia, inguinal (groin) hernia, enlarged liver and spleen, and developmental delay in 15% of cases. The AR form appears to be more severe, with the kidney anomalies, congenital heart defects, vertebral defects, rib fusions, scoliosis, and cognitive delays occurring more commonly in that form. The AR form has clefting of the distal phalanges (mainly thumbs), which the AD form does not. *Cause:* Mutations in *ROR2* (9q22), *DVL1* (1p36.33), *WNT5A* (3p14.3), and *DVL3* (3q27.1). *Inheritance:* AD, AR. *Prevalence:* Rare.

Russell-Silver syndrome (Silver-Russell syndrome) *Disease category:* Imprinting defect/multiple congenital anomalies. *Clinical features:* Short stature (beginning with intrauterine growth retardation); skeletal asymmetry with hemihypertrophy (enlargement of one side of the body) in 60%; triangular facies, beaked nose, thin upper lip, narrow, high-arched palate, blue sclerae, occasional café-au-lait spots, and fifth-finger clinodactyly; genital anomalies in males; and motor and cognitive developmental delay and learning disabilities. *Associated complications:* Delayed fontanelle (soft spot) closure, hypocalcemia (low blood calcium level) in neonatal period with sweating and rapid breathing, increased risk of fasting hypoglycemia (low blood sugar level) as a toddler, feeding difficulties, precocious sexual development, and vertebral anomalies. *Cause:* 30%–60% of patients have a hypomethylation of the imprinting control region

1 (ICR1) in 11p15.5, affecting the expression of *H19* and *IGF2*; 5%–10% of patients carry a maternal uniparental disomy of chromosome 7. Chromosomal rearrangements have also been reported. There is still a large proportion of patients with an unknown cause. *Inheritance*: NM with AD inheritance when passed from an affected individual; maternal uniparental disomy; AR in rare cases. Recurrence risk is generally low but can be increased in cases of familial epimutations or chromosomal rearrangements. *Incidence*: 1:30,000–1:100,000.

Sandifer syndrome (SS) *Disease Category*: Neurological *Clinical Features*: Sudden-onset dystonic movements with arching of the back, rigid posturing, torticollis (wry neck), laterocollis, (uncontrolled

tilting of the neck from side to side), or retrocollis (uncontrolled backward tilting of the head). Children are often misdiagnosed with seizures or a movement disorder. *Cause*: Rare complication of gastroesophageal reflux disease (GERD). *Treatment*: Symptoms generally improve after antireflux medication and/or Nissen fundoplication, a surgical procedure in which the upper portion of the stomach is wrapped around the lower end of the esophagus to prevent reflux. Amino-acid based formula was successful in two patients refractory to other therapies.

Scheie syndrome (MPS V) *See* mucopolysaccharidoses.

Severe combined immunodeficiency (SCID) *Disease category*: Immunodeficiency. *Clinical Features*: Low to absent T and natural killer (NK) lymphocytes and nonfunctional B lymphocytes, failure to thrive, oral/diaper candidiasis (a fungal infection, also called thrush), absent tonsils and lymph nodes, recurrent infections, and persistence of infections despite conventional treatment. *Associated complications*: Rashes, diarrhea, cough, congestion, fever, pneumonia, sepsis, and other severe bacterial infections. *Cause*: Mutations in *IL2RG* (Xq13.1), adenosine deaminase deficiency due to mutations in *ADA* (20q13.12), mutations in *RAG1* (11p12), *RAG2* (11p12), *JAK3* (19p13.11), *IL7R* (5p13.2), *PTPRC* (1q31.3-q32.1), *DCLRE1C* (10p13), *CD3D* (11q23.3), *CD3E* (11q23.3), *CD247* (1q24.2), *PRKDC* (8q11.21), *AK2* (1P35.1), *CORO1A* (16p11.2). *Inheritance*: AR, XLR. *Prevalence*: 1:50,000–1:100,000. *Treatment*: Bone marrow transplant prior to the development of symptoms. Interim management includes treatment of infections and use of immunoglobulin infusions and antibiotics, particularly prophylaxis against *Pneumocystis jiroveci* and fungal infection. Newborn screening currently tests for SCID, allowing for earlier treatment.

Sly syndrome (MPS VII) See mucopolysaccharidoses.

Smith-Lemli-Opitz syndrome *Disease category:* Inborn error of metabolism-cholesterol synthesis. *Clinical features:* Microcephaly, short nose with upturned nostrils, low serum cholesterol, syndactyly of second and third toes, genitourinary abnormalities, kidney anomalies, and lung malformations. *Associated complications:* Intrauterine growth restriction, postnatal growth retardation, hypotonia, moderate to severe intellectual disability, motor and language delay, seizures, feeding difficulties and vomiting, photosensitivity, and occasional congenital heart defect. Behavioral problems include irritability, sleep disturbance, and self-injurious behavior. *Cause:* Defect in cholesterol metabolism (conversion of 7-DHC to cholesterol) caused by mutations in *DHCR7* (11q12–q13). Clinical features result from deficiency of cholesterol as well as toxic accumulation of 7-DHC. *Inheritance:* AR. *Prevalence:* 1:20,000–1:40,000. *Treatment:* Dietary modifications, including cholesterol supplementation. Simvastatin has been shown to be well tolerated and to improve the dehydrocholesterol-to-total sterol ratio and irritability symptoms.

Smith-Magenis syndrome (SMS) *Disease category:* Multiple congenital anomalies/contiguous gene syndrome. *Clinical features:* Feeding difficulties; poor weight gain; hypotonia; hyporeflexia; lethargy; distinctive facial features; developmental delay; cognitive impairment and significant behavioral abnormalities, including sleep disturbance; stereotypies, such as a “self-hug” and “lick and flip” (licking their fingers and flipping pages of books and magazines); and self-injurious behavior, including self-hitting and self-biting. *Associated complications:* Skeletal anomalies, short stature, brachydactyly (short fingers and toes), ophthalmologic abnormalities, otolaryngologic abnormalities, peripheral

neuropathy, and cardiac and kidney anomalies. *Cause:* Microdeletion at chromosome 17p11.2 or mutations, including the gene *RAI1*. *Inheritance:* Most cases represent new mutations with AD inheritance when passed from an affected individual. *Prevalence:* 1:25,000.

Stickler syndrome (hereditary progressive arthroophthalmopathy) *Disease category:* Connective tissue disorder. *Clinical features:* Flat facies, myopia, cleft of hard or soft palate, and spondyloepiphyseal dysplasia (disorder of bone growth that results in dwarfism, characteristic skeletal abnormalities, and occasionally problems with vision and hearing). *Associated complications:* Hypotonia, hyperextensible joints, occasional scoliosis, risk of retinal detachment, cataracts, arthropathy (joint disease) in late childhood or adulthood, and occasional hearing loss or cognitive impairment. *Cause:* Mutations in type 2, type 9, and type 11 procollagen genes (*COL2A1*, *COL9A1*, *COL11A1*, and *COL11A2*), which have been linked to chromosomes 12q13.11–q13.2, 6q13, 1p21,

and 6p21.3, respectively. *Inheritance*: AD with variable expression, AR (*COL9A1* mutations). *Prevalence*: 1:7,500–1:9,000.

References: Higuchi, Y., Hasegawa, K., Yamashita, M., Tanaka, H., & Tsukahara, H. (2017). A novel mutation in the *COL2A1* gene in a patient with Stickler syndrome type 1: A case report and review of the literature. *Journal of Medical Case Reports*, 11(1), 237.

Tay-Sachs disease (GM2 gangliosidosis, type I) *Disease category*: Inborn error of metabolism: lysosomal storage disease. *Clinical features*: A lysosomal storage disorder leading to a progressive neurological condition characterized by deafness, blindness, and

seizures; development is typical for the first several months of life. Subsequently, there is an increased startle response, hypotonia followed by hypertonia, a cherry-red spot in the maculae, and optic nerve atrophy. There is rapid decline and fatality by age 5 years. An adult form of this enzyme deficiency presents with ataxia. *Associated complications*: Feeding abnormalities and aspiration. *Cause*: Deficiency of the enzyme hexosaminidase A caused by mutation in *HEXA* (15q23–q24). *Inheritance*: AR. *Prevalence*: 1:112,000; 1:3,600 in the Ashkenazi Jewish population (although extensive genetic counseling of carriers identified through carrier screening programs has led to a reduction of this disorder by more than 90% in this population); increased frequency in the Cajun and French Canadian populations.

tetrasomy X *See* XXXX syndrome.

thrombocytopenia-absent radius syndrome (TAR syndrome) *Disease category*: Multiple congenital anomalies. *Clinical features*: Radial aplasia (absence of one of the lower arm bones) with normal thumbs; thrombocytopenia (platelet deficiency) is present in all cases and symptomatic in 90% of cases; and 50% of patients have dysmorphic features, including micrognathia (small jaw) and low posteriorly rotated ears. *Associated complications*: Knee joint abnormalities, neonatal foot swelling, occasional congenital heart or kidney defect, gastrointestinal bleeding, and occasional intracerebral bleeding. *Cause*: Compound heterozygous for a mutation in *RBM8A* and a minimal 200-kb deletion at 1q21.1. *Inheritance*: AR. In 25%–50% of cases, the deletion is *de novo*. *Prevalence*: 1:100,000–1:200,000. *Treatment*: Platelet infusions.

References: Manukjan, G., Bosing, H., Schmugge, M., Strauss, G., & Schulze, H. (2017). Impact of genetic variants on haematopoiesis in patients with thrombocytopenia absent radii (TAR) syndrome. *British Journal of Haematology*, 179(4), 606–617.

Tourette syndrome (Gilles de la Tourette syndrome) *Disease category:* Neurological disorder. *Clinical features:* Chronic vocal or motor tics (irrepressible, repetitive, and nonrhythmic movements and vocalizations) present for at least 1 year, obsessive-compulsive disorder (OCD), and attention-deficit/hyperactivity disorder (ADHD). Age of onset is typically between 3–8 years of age, with onset of motor tics most often preceding vocal tics. The course of the tics is waxing and waning, and peak symptom intensity is usually in late childhood (mean age 10 years). Fluctuation occurs in adolescence, and by early adulthood there is often significant improvement. *Associated complications:* Learning difficulties, language-based learning problems, habit disorders such as trichotillomania (chronic hair pulling), pathologic nail biting and skin picking, mood disorders such as bipolar disorder and major depressive disorder, and anxiety. *Cause:* Unknown; *SLITRK1* has been implicated as a candidate gene but studies have not been conclusive. Environmental factors are thought to be involved as well since the concordance rate is not 100% between monozygotic twins. Likely genetically heterogeneous. *Inheritance:* Unknown, thought to be AD. *Prevalence:* 0.3%–1% of the population. Males are affected more often than females, with an approximate four-to-one ratio. *Treatment:* Typical and atypical neuroleptics such as haloperidol and pimozide, alpha adrenergic agonists such as clonidine, habit reversal therapy, surgical intervention for a small subset with intractable Tourette disorder, and repetitive transcranial magnetic stimulation. New agents such as valbenazine, delta-9-tetrahydrocannabinol, and ecopipam are being investigated. Deep brain stimulation has shown improvement in symptoms but also has a large percentage of adverse events.

TP63-related disorders *Disease category:* Ectodermal dysplasia. *Clinical features:* TP63-related disorders comprise six phenotypes, including ankyloblepharon-ectodermal defects-cleft lip/palate syndrome, Acro-dermo-ungual-lacrimar-tooth (ADULT) syndrome, ectrodactyly, ectodermal dysplasia, cleft lip/palate syndrome 3 (EEC3), limb-mammary syndrome, split-hand/foot malformation type 4 (SHFM4), and isolated cleft lip/cleft palate (orofacial cleft 8). Individuals have varying combinations of ectrodactyly (split hands or feet), ectodermal dysplasia (abnormal skin development), sparse hair, cleft lip and palate, and lacrimal (tear) duct abnormalities; intelligence is not usually affected. *Associated complications:* Occasional kidney or genital anomalies, hearing impairment, hypodontia (underdeveloped teeth), hypoplastic (underdeveloped) breasts, alopecia (areas of hair loss), hypospadias (opening of the urethra is on the underside of the penis), and lymphoma associated with EEC3 only. *Cause:* Mutations in *TP63* (3q27). *Inheritance:* AD with variable penetrance and expressivity; 30% have an affected parent, and 70% have a *de novo* mutation. *Prevalence:* Unknown.

Treacher Collins syndrome (mandibulofacial dysostosis) *Disease category:* Multiple congenital anomalies. *Clinical features:* Characteristic facial appearance with malformation of external ears, small chin, flattened midface, and cleft palate. *Associated complications:* Conductive or mixed (conductive and sensorineural) hearing loss, defects of middle and inner ear, respiratory and feeding problems, and apnea; intelligence is average in 95% of cases. *Cause:* 78%–93% of patients have mutations in *TCOF1* (5q32–q33), approximately 8% have mutations in *POL1C* (6p21.1) or *POLR1D* (13q12.2). *Inheritance:* AD; 60% NM. AR occurs in a very small proportion of patients (1%). *Incidence:* 1:10,000–1:50,000. *Treatment:* Surgical repair of most malformations.

References: Kadakia, S., Helman, S. N., Badhey, A. K., Saman, M., & Ducic, Y. (2014). Treacher Collins syndrome: The genetics of a craniofacial disease. *International Journal of Pediatric Otorhinolaryngology*, 78(6), 893–898.

trisomy 18 syndrome (Edwards syndrome) *Disease category:* Chromosome abnormality/Multiple congenital anomalies. *Clinical features:* Prenatal onset of growth retardation, low-set ears, clenched fists, “rocker-bottom” feet, congenital heart defects, microphthalmia, coloboma, and corneal opacity; 30% die within first month of life, 50% die by the second month, and only 10% survive their first year. *Associated complications:* Feeding problems, aspiration pneumonia, conductive hearing loss, and profound intellectual disability. *Cause:* Nondisjunction resulting in extra chromosome 18. *Inheritance:* NM; usually a nondisjunction chromosomal abnormality. May recur in families in the presence of parental translocation. *Incidence:* 1:7,500 births.

trisomy X See XXX syndrome.

tuberous sclerosis complex *Disease category:* Neurologic. *Clinical features:* Hypopigmented areas on skin, adenoma sebaceum (acne-like facial lesions), infantile spasms, iris depigmentation, retinal defects, calcium deposits in brain, benign tumor of the kidneys, and pulmonary lesions. *Associated complications:* Seizures, mild to moderate intellectual disability, tumors of the heart, increased risk of malignancy, hypoplastic tooth enamel and dental pits, kidney cysts, and hypertension. *Cause:* Mutations in *TSC1* (16p13) and *TSC2* (9q34); 10% of patients have no variant identified. *Inheritance:* AD with variable expressivity; two thirds of cases are NM. *Incidence:* 1:5,800. *Treatment:* mTOR inhibitors have shown improvement for multiple symptoms. Vigabatrin and other antiepileptics are used for seizures.

Turner syndrome (45,X; monosomy X) *Disease category:* Chromosome abnormality. *Clinical features:* Affecting females only, the physical features include short stature, broad chest with widely spaced nipples, short neck with low hairline and extra skin at nape (“webbed” appearance), and “puffy” hands and feet. *Associated complications:* “Streak” ovaries causing infertility and delayed puberty, congenital heart defect (often coarctation of aorta), small ear canals, eye involvement (strabismus, ptosis, nystagmus, and cataracts), chronic otitis media in 90% with frequent hearing loss, hypothyroidism, and kidney disease; intelligence is usually average, but the prevalence of learning disabilities is high. *Cause:* Nondisjunction chromosome abnormality resulting in one copy of the sex chromosome. *Inheritance:* NM; usually nondisjunction chromosomal abnormality. *Prevalence:* 1:4,000. *Incidence:* 1:2,000. *Treatment:* Growth hormone has been used successfully to increase eventual adult height. Hormone replacement therapy is needed to initiate puberty (see also Chapter 1).

urea cycle disorders *Disease category:* Inborn error of metabolism: amino acid. *Clinical features:* This group of disorders results from defects in any of the first five enzymes in the urea cycle (CPSI, OTC, ASS, ASL, and ARG) or the cofactor producer (NAGS), which break down the excess nitrogen from protein degradation. Severe deficiencies or complete absence of the first four enzymes results in the accumulation of ammonia and other precursor metabolites during the first few days of life. Infants often appear normal initially but rapidly develop lethargy, vomiting, anorexia, hyperventilation or hypoventilation, hypothermia, seizures, neurologic posturing, cerebral edema/encephalopathy, and coma. Partial urea cycle enzyme deficiencies are milder, and ammonia accumulation may be triggered by illnesses or stress at almost any time of life, thus delaying diagnosis by months to years. Deficiency of the fifth enzyme in the pathway causes arginase deficiency, which does not typically have the same frequency of hyperammonemic episodes but results in seizures, intellectual disability, and severe spasticity. Citrin deficiency and hyperornithinemia, hyperammonemia, and homocitrullinuria (HHH) syndrome also occur due to defects in two transporters. *Associated complications:* Loss of appetite, cyclical vomiting, lethargy, behavioral abnormalities, delusions, hallucinations, and psychosis can occur during hyperammonemic episodes. Developmental delay, attention-deficit/hyperactivity disorder, and intellectual disability are common, especially in those patients who have had significantly elevated ammonia levels. Liver failure occurs in some patients. *Cause:* Mutations or deletions involving the genes encoding the enzymes and the cofactor and transporter proteins of the urea cycle. *Inheritance:* AR, except OTC, which is X-linked. *Prevalence:* 1:30,000, although undiagnosed partial defects may make the number much higher. *Treatment:* Hemodialysis for rapidly lowering ammonia levels, ammonia scavenging medications (intravenous for acute hyperammonemia and oral for daily use), restricted-protein diet to reduce excess nitrogen, amino acid supplementation, and liver transplantation in those with recurrent hyperammonemia or significant liver disease. Gene therapy is currently being studied for OTC deficiency.

Usher syndrome *Disease category:* Auditory/ophthalmologic. *Clinical features:* Approximately 10 subtypes exist; all have progressive sensorineural deafness, nystagmus, retinitis pigmentosa, and central nervous system defects (e.g., loss of sense of smell, vertigo, and epilepsy). Type 1 is characterized by profound hearing loss, absent vestibular function, and retinitis pigmentosa (eye disease characterized by black pigmentation and gradual degeneration of the retina) in childhood. Individuals with type 2 have normal vestibular function and less severe hearing loss, with onset of retinitis pigmentosa in the second decade. Type 3 can be differentiated by the presence of a progressive loss of hearing. *Associated complications:* Ataxia, psychosis, cataracts, and occasional cognitive impairment; more than 50% of adults with a combination of congenital blindness and deafness have Usher syndrome. *Cause:* Six genes have been linked to type I: *MYO7A*, *USH1C*, *CDH23*, *PCDH15*, *USH1G*, and *CIB2*. Three genes are associated with type II: *USH2A*, *WHRN*, and *ADGRV1CLRN1*. *HARS* has been linked to type III. *Inheritance:* AR. *Prevalence:* 3.2:100,000–6.2:100,000. *Treatment:* Cochlear implants may be beneficial for some individuals with type 1, while hearing aids are effective for individuals with type 2.

VATER/VACTERL association *Disease category:* Multiple congenital anomalies. *Clinical features:* VATER is a nonrandom group of malformations that co-occur, including vertebral defects (V), anal atresia (imperforate anus) (A), tracheoesophageal fistula (a problem with the connection between the trachea and esophagus) (TE), and kidney anomalies (R).

VACTERL is an expanded definition that includes cardiac malformations (C) and limb anomalies (L). Diagnosis is made if three of seven defects are present. *Associated complications*: Poor weight gain, ear anomalies, facial clefting, respiratory complications, genitourinary anomalies, and radial (lower arm bone) and other limb defects. Intelligence is usually not affected. *Cause*: Likely genetically heterogeneous, and multiple candidate genes are being investigated. *Inheritance*: Usually SP, no recognized genetic or teratogenic cause; rare families with AR pattern. *Prevalence*: 1.6:10,000.

velocardiofacial syndrome (VCFS) See chromosome 22q11 microdeletion syndromes.

von Recklinghausen disease See neurofibromatosis, type I.

Waardenburg syndrome *Disease category*: Auditory/pigmentary. Four clinical subtypes exist with types I and II accounting for the majority of cases. *Clinical features*: Widely spaced eyes (type I), heterochromia (irises of different colors), white hair forelock, non-progressive sensorineural hearing loss, and musculoskeletal abnormalities (type III). Types I and II have virtually identical clinical features, with the only distinguishing characteristic being telecanthus (an abnormally long distance from the inside corner of the eye to the nose), which is found in type I but not in type II. Type III has telecanthus (increased distance between the corners of the eyes) and upper limb abnormalities. Type IV (also known as Waardenburg-Shah syndrome) has the additional feature of Hirschsprung disease (a condition with congenital missing nerve cells in the muscles of the colon, leading to difficulty passing stool). *Associated complications*: Impaired vestibular function leading to ataxia, premature graying, vitiligo (patches of skin depigmentation), and occasional glaucoma. *Cause*: Types I and III: mutations in *PAX3* (2q35); type II: mutations

in *MITF* (3p14.1–p12.3), *WS2B* (1p21–p13.3), *WS2C* (8p23), *SNAI2* (8q11.21), and *SOX10* (22q13.1); type IV: mutations in *EDNRB* (13q22), *EDN3* (20q13), and *SOX10* (22q13). *Inheritance*: AD, AR. *Prevalence*: 1:20,000–1:40,000.

Williams syndrome *Disease category*: Multiple congenital anomalies/contiguous gene. *Clinical features*: Characteristic “elfin” facies (full lips and cheeks and fullness of area around the eyes), short stature, starlike pattern to iris, hoarse voice, communication delays in early childhood followed by increasing verbal abilities later in life, friendly, talkative, extroverted personality, congenital heart defect, and often supravalvular aortic stenosis. *Associated complications*: Hypercalcemia (increased blood calcium level), stenosis (stricture) of blood vessels, kidney anomalies, hypertension, joint contractures, and mild to moderate intellectual disability (but with characteristic strength in verbal abilities). *Cause*: Microdeletion of a segment of chromosome 7q11.23 consisting of approximately 28 genes. *Inheritance*: AD; all cases

are the result of NM (sporadic deletions). *Prevalence*: 1:7,500–1:8,000.

Wilson disease *Disease category*: Inborn error of metabolism: copper. *Clinical features*: Liver dysfunction, jaundice, Kayser-Fleischer ring (dark ring that appears to encircle the iris of the eye due to copper deposition) in cornea, and low serum ceruloplasmin (an enzyme that is important in the regulation of copper in the body). *Associated complications*: Movement disorders, dysphagia (difficulty swallowing) or other oral-motor dysfunctions, and behavioral disturbances; if left untreated, death from liver failure within 1–3 years of onset. *Cause*: Mutations in the copper metabolism gene *ATP7B* (13q14.3–q21.1), which lead to intracellular accumulation of copper in the liver. *Inheritance*: AR. *Prevalence*: 1:30,000; as high as 1:10,000 in China, Japan, and Sardinia. *Treatment*: Administration of copper-chelating agents in conjunction with a low-copper diet. Liver transplant is used in those who fail to respond to medical therapy.

Wolf-Hirschhorn syndrome *Disease category*: Multiple congenital anomalies/contiguous gene. *Clinical features*: Hypertelorism (widely spaced eyes); characteristic broad, beaked nose ("Greek warrior helmet appearance"), downturned mouth, short philtrum (vertical groove between the base of the nose and the border of the upper lip), microcephaly, marked intrauterine growth retardation and premature birth, ear anomalies, and severe intellectual disability with reductions in receptive and expressive language. *Associated complications*: Hypotonia, psychomotor delays, growth delay, kidney anomalies, hypodontia (decreased number of teeth) resulting

in feeding problems, seizures, and occasional heart defect or cleft palate. *Cause*: Heterozygous deletion of the Wolf-Hirschhorn syndrome critical region (WHSCR) on 4p16.3. *Inheritance*: Occurs as a result of a NM; recurrence risk is greater if parent has a balanced translocation. *Prevalence*: 1:50,000.

X-linked ALD *See* adrenoleukodystrophy.

XXX (trisomy X; 47,XXX); XXXX (tetrasomy X); and XXXXX (pentasomy X) syndromes *Disease category*: Chromosome abnormality. *Clinical features*: Females with XXX syndrome generally have above-average stature but otherwise typical physical appearance; 70% have significant learning disabilities. Language delay/problems are also present in some girls. Significant malformations have been described in some patients, including gonadal dysgenesis (nonfunctional ovaries), a dysmorphic facial appearance, atrophic or dysplastic (absent or shrunken) kidneys, and vaginal and uterine malformations. XXXX syndrome is associated with a mildly unusual facial appearance, behavioral problems, and moderate intellectual disability. XXXXX syndrome presents with severe intellectual disability and multiple physical defects. *Associated complications*: Infertility and delayed pubertal development. *Cause*: Nondisjunction during meiosis. *Inheritance*: NM; usually nondisjunction chromosomal abnormality, may recur in families in the presence of parental translocation. *Incidence*: 1:800 live-born females.

prenatal versus postnatal diagnosis. *American Journal of Medical Genetics, Part A*, 170(11), 2870–2881.

XXY syndrome See Klinefelter syndrome.

XXX syndrome *Disease category:* Chromosome abnormality. *Clinical features:* Subtle findings, including a tall stature, severe acne, and large teeth. *Associated complications:* Poor fine-motor coordination; learning disabilities; language delay; varying degrees of behavioral disturbances, including tantrums and aggression; and increased risk for autism. *Cause:* Extra Y chromosome resulting from nondisjunction. *Inheritance:* NM; usually nondisjunction chromosomal abnormality, may recur in families in presence of parental translocation. *Prevalence:* 1:1,000.

Zellweger spectrum disorder (ZSD) *Disease category:* Peroxisomal disorder (see adrenoleukodystrophy

[X-linked ALD] for the childhood form). *Clinical features:* A disorder of peroxisome biogenesis and an intermediate presentation of the Zellweger syndrome spectrum. Peroxisomes are minute organelles in certain cells that are involved in the processing of long-chain fatty acids. ZSD can present in the neonatal period but generally comes to attention later in childhood because of developmental delays, hearing loss, or visual impairment. The condition is slowly progressive, and hearing and vision worsen with time. Some individuals may develop progressive degeneration of myelin, a leukodystrophy, which may lead to loss of previously acquired skills and eventually death. *Associated complications:* Intellectual disability, cataracts, visual and auditory impairment, liver dysfunction, hypotonia, and hemorrhage/intracranial bleeding. *Cause:* Mutations in 13 different *PEX* genes, resulting in the absence of peroxisomes, have been identified. *Inheritance:* AR. *Prevalence:* 1:50,000–1:80,000, with variation among populations.

APPENDIX **C**

Commonly Used Medications

Dimitrios A. Savva, Shogo John Miyagi, and
Johannes N. van den Anker

This appendix contains information about commonly used medications but is not meant to be used to prescribe medication. The generic name of each drug is in capital letters. The trade name is in parentheses; not all preparations are included. The drug categories, uses, standard applications, and common side effects are listed. Commonly used medications are listed in alphabetical order by generic drug name (see Table C.1), drug class (see Table C.2), and brand name (see Table C.3). Please note that uses and standard applications may change during the life of this edition and that additional side effects may be discovered. Specific drug interactions

and contraindications such as hepatic or renal (kidney) insufficiency are not included; use of any medication should be discussed with a health care provider familiar with the individual's medical background.

Table C.1. Commonly used medications, alphabetized by generic drug name

Medication	Category	Use(s)	Standard applications	Side effects
ACETAMINOPHEN (Tylenol)	Analgesic, Antipyretic	Used to treat fever and pain	CAP, LIQ, TAB, SUPP, IV: 10–15 mg/kg/dose three to four times daily; max 75 mg/kg/day or 3,000 mg/day	Rash, hepatotoxicity, renal dysfunction
ACETAZOLAMIDE (Diamox)	Anticonvulsant, diuretic, carbonic anhydrase inhibitor	Used to treat metabolic alkalosis, glaucoma, edema, pseudotumor cerebri	CAP, LIQ, TAB, IV: 5 mg/kg/dose three to four times daily	Flushing, skin reaction/rash, electrolyte imbalance
ACYCLOVIR (Zovirax)	Antiviral agent	Used primarily to treat or prevent infections caused by herpes simplex viruses or varicella	CAP, LIQ, TAB, TOP, IV: Doses vary with clinical situation	Renal dysfunction, headache, gastrointestinal irritation, hepatotoxicity
ALBUTEROL (Ventolin)	Beta 2 agonist bronchodilator	Asthma	INH: Dose varies with clinical situation	Increased heart rate, hypokalemia, shakiness, excitability
ALPRAZOLAM (Xanax, Xanax XR)	Benzodiazepine	Anxiety, panic attacks	TAB, LIQ: <18 yo: Initial dose of 0.125 mg/dose three times daily; safety and efficacy in children <18 yo are not known ≥18 yo: Initial dose of 0.25–0.5 mg/dose three times daily; max 4 mg/day	Drowsiness, fatigue, depression, decreased salivation, dysarthria, ataxia, addictive potential Avoid abrupt withdrawal
AMITRIPTYLINE (Elavil)	Tricyclic antidepressant	Depression, migraine prophylaxis, neuropathic pain, anxiety	TAB, IV: ≥12 yo: 0.33–0.5 mg/kg/dose three times daily; not recommended for children <12 yo Chronic pain management: Initial dose of 0.1 mg/kg/dose once daily, increase to max 2 mg/kg/dose	Sedation, dry mouth, blurred vision, dizziness, urinary retention, confusion, cardiac arrhythmia (rarely)
AMOXICILLIN (Amoxil)	Antibiotic, penicillin	Treatment of susceptible infections most commonly acute otitis media, upper or lower respiratory tract	CAP, CHEW, TAB, LIQ: Doses vary with clinical situation	Diarrhea, rash, nausea, allergic reactions
AMOXICILLIN/CLAVULANIC ACID (Augmentin, Augmentin ES, XR)	Antibiotic, penicillin	Treatment of susceptible infections most commonly acute otitis media, upper or lower respiratory tract	TAB, LIQ, CHEW: Doses vary with clinical situation Use 600 mg or 42.9 mg per 5 mL suspension formulation with high doses	Diarrhea, rash, nausea
AMPHETAMINE salts (Adderall, Adderall XR)	Stimulant	Attention-deficit/hyperactivity disorder, narcolepsy	CAP, TAB, LIQ: One to three times daily; not recommended for <3 yo 3–5 yo: Initial dose of 2.5 mg/dose once daily; increase of 2.5 mg/week until optimal response ≥6 yo: Initial dose of 5 mg/dose once or twice daily; increase of 5 mg/week until optimal response; extended release is dosed once daily	Insomnia, loss of appetite, emotional instability, addictive potential, arrhythmia, visual disturbances Caution in seizure and cardiac patients
ARIPIPRAZOLE (Abilify)	Antipsychotic, atypical	Bipolar disorder, agitation, psychosis, Tourette syndrome, autism spectrum disorder	TAB: Initial dose of 2 mg/dose once daily, increase of 5 mg/week until optimal response; max 30 mg/day	Nausea, weight gain, akathisia, somnolence, extrapyramidal effects, fatigue, blurred vision

Medication	Category	Use(s)	Standard applications	Side effects
ATOMOXETINE (Strattera)	Norepinephrine reuptake inhibitor, selective	Attention-deficit/hyperactivity disorder	CAP: Initial dose of 0.5 mg/kg/dose once daily, increase after minimum of 3 days to 1.2 mg/kg/day; can divide dose into twice daily; max 1.4 mg/kg/day or 100 mg/day	Headache, palpitations, decreased appetite, abdominal pain, nausea, vomiting, weight loss, hepatotoxicity
AZITHROMYCIN (Zithromax)	Antibiotic, macrolide	Drug used against staphylococcal infections, strep throat, community acquired pneumonia, acute otitis media	TAB, LIQ, IV: 10 mg/kg/dose once daily on Day 1 (max 500 mg), then 5 mg/kg/dose once daily on Days 2–5 (max 250 mg)	Hepatotoxicity, nausea, vomiting, diarrhea, dermatitis, fever, drug–drug interactions
BACLOFEN (Lioresal)	Skeletal muscle relaxant	Spasticity of cerebral or spinal origin	TAB, LIQ, IT: Oral: Initial dose of 5 mg two or three times daily; increase of 5 mg every 4–7 days; max 30–80 mg/day Intrathecal: 50–600 mcg/day delivered by implantable pump	Drowsiness, muscle weakness, constipation, dizziness, paresthesia Avoid abrupt withdrawal
BENZTROPINE (Cogentin)	Anticholinergic	Movement disorders associated with antipsychotics such as haloperidol	TAB, IV: Initial dose of 0.02–0.05 mg/kg/dose; increase of 0.5 mg/dose twice daily; max 6 mg/day	Gastrointestinal upset, drowsiness, dizziness, blurred vision, dry mouth, difficult urination, constipation, tachycardia
BOTULINUM TOXIN A (Botox)	Antispasticity agent	Spasticity in cerebral palsy and spinal cord injury, strabismus, migraines	IM: 4 units/kg divided between affected limbs every 2–3 months; injections are administered by a qualified practitioner	Diffuse skin rash, paralysis with over-dose, muscle weakness
BUDESONIDE (Pulmicort, Rhinocort)	Corticosteroid	Maintenance and prophylactic treatment of asthma, rhinitis, nasal polyps, Crohn's disease	INH: Doses vary with clinical situation	Nausea, cough, oral candidiasis, hoarseness, dry mouth, epistaxis
BUPROPION (Wellbutrin, SR, XL, Zyban)	Antidepressant (dopamine re-uptake inhibitor)	Depression, attention-deficit/hyperactivity disorder, smoking cessation	TAB: Safety and efficacy in <18 yo have not been established; limited evidence >6 yo: 6 mg/kg/day; max 300 mg/day	Decreased seizure threshold, nausea, agitation, anxiety, insomnia, decreased appetite, tachycardia Increased suicidal risks in children and adolescents
BUSPIRONE (Buspar)	Antianxiety agent	Anxiety, aggression, depression, attention-deficit/hyperactivity disorder	TAB: Safety and efficacy in children <18 yo have not been established	Chest pain, ringing in the ears, dizziness, drowsiness, restlessness, dyskinesia
CALCIUM CARBONATE	Antacid, electrolyte supplement	Relief of acid indigestion, calcium supplementation	CAP, TAB, LIQ: Doses vary based on clinical scenario	Abdominal pain, constipation, nausea, vomiting
CALCIUM GLUCONATE	Electrolyte supplement	Treatment of hypocalcemia and conditions secondary to hypocalcemia or hyperkalemia	CAP, TAB, LIQ, IV: Doses vary based on clinical scenario	IV: Arrhythmia, heat waves, bradycardia Oral: Constipation

(continued)

Table C.1. (continued)

Medication	Category	Use(s)	Standard applications	Side effects
CARBAMAZEPINE (Tegretol, Tegretol XR)	Anti-seizure medication	Epilepsy-partial, generalized or mixed seizures, bipolar disorder, neuralgia, agitation	CAP, TAB, LIQ, CHEW: <6 yo: Initial dose of 10–20 mg/kg/day divided two to three times daily; max 35 mg/kg/day 6–12 yo: Initial dose of 200 mg/dose twice daily, increase of 200 mg/week; max 1,200 mg/day	Unsteady gait, double vision, drowsiness, slurred speech, dizziness, tremor, headache, nausea, drug interactions, aplastic anemia, agranulocytosis, rash
CARNITINE (Carnitor)	Nutritional supplement	Primary and secondary carnitine deficiency, especially in inborn errors of metabolism	TAB, LIQ, IV: 12.5–25 mg/kg/dose every 6 hours; max 3,000 mg/day	Nausea, vomiting, abdominal cramps, diarrhea, body odor, chest pain, headaches, hypertension with IV
CEFDINIR (Omnicef)	Antibiotic, cephalosporin	Wide spectrum of coverage; used to treat acute otitis media, sinusitis, skin infections, community-acquired pneumonia	CAP, LIQ: 7 mg/kg/dose twice daily or 14 mg/kg/dose once daily; max 600 mg/day	Headache, rash, abdominal pain, nausea, vomiting
CEFPODOXIME	Antibiotic, cephalosporin	Wide spectrum of coverage; used to treat acute otitis media, sinusitis, skin infections, community-acquired pneumonia	TAB, LIQ: 5 mg/kg/dose every 12 hours for 5–10 days; max 200 mg/dose	Headache, rash, abdominal pain, nausea, vomiting
CEPHALEXIN (Keflex)	Antibiotic cephalosporin	Used to treat susceptible infections of the respiratory tract, skin, and urinary tract; prophylaxis against infective endocarditis	CAP, TAB, LIQ: Doses vary based on clinical scenario	Headache, rash, nausea, vomiting, diarrhea, hypersensitivity
CETIRIZINE (Zyrtec)	Antihistamine, alpha/beta agonist decongestant	Allergies, itching	TAB, LIQ, CHEW: 6–12 mo: 2.5 mg daily 12 mo–2 yo: 2.5 mg once daily 2–5 yo: 5 mg once daily >6 yo: 10 mg daily	Dry mouth, headache, nausea, somnolence
CHLORPROMAZINE (Thorazine)	Antipsychotic, typical	Psychosis, anxiety, aggression, intractable hiccups, nausea/vomiting, hyperexcitable behavior	TAB, LIQ, IV: Doses vary based on clinical scenario	Drowsiness, tardive dyskinesia, hypotensive, weight gain, lower seizure threshold, depletion of white blood cells, rash
CHLOROTHIAZIDE (Diuril)	Diuretic, thiazides	Diuresis	TAB, LIQ, IV: IV: 2.5–5 mg/kg/dose twice daily Oral: 5–20 mg/kg/dose twice daily	Electrolyte imbalances
CIPROFLOXACIN (Cipro)	Antibiotic, fluoroquinolone	Treatment/prophylaxis of susceptible infections, (i.e., urinary tract infections, lower respiratory tract infections)	TAB, LIQ, IV: 10–20 mg/kg/dose twice daily; max 500 mg/dose	Hepatotoxicity, diarrhea, abdominal pain Avoid with calcium-containing products
CITALOPRAM (Celexa)	Antidepressant (selective serotonin reuptake inhibitors)	Depression, panic disorder, obsessive-compulsive disorder	TAB, LIQ: 7–11 yo: 10 mg/dose once daily; increase of 5 mg every 2 weeks; max 40 mg/day ≥12 yo: 20 mg/dose once daily, increase of 10 mg every 2 weeks; max 40 mg/day	Somnolence, insomnia, nausea, dry mouth, increased sweating, agitation, restlessness Increased suicidal risks in children and adolescents

Medication	Category	Use(s)	Standard applications	Side effects
CLARITHROMYCIN (Biaxin, XL)	Antibiotic, macrolides	Wide-spectrum drug used against staphylococcal infection, strep throat, and mycoplasma infections	TAB, LIQ: 7.5 mg/kg/dose twice daily; max 500 mg/dose	Stomach upset, diarrhea, nausea, cardiac arrhythmias, drug interactions
CLOMIPRAMINE (Anafranil)	Tricyclic antidepressant	Obsessive-compulsive disorder, trichotillomania	CAP: Initial dose of 10–25 mg/day; max 3 mg/kg/day or 200 mg/day	Drowsiness, dry mouth, blurred vision, flushing, constipation, central nervous system depression
CLONAZEPAM (Klonopin)	Benzodiazepine	Seizures, infantile spasms, anxiety, panic disorders	TAB, ODT: Initial dose of 0.005–0.1 mg/kg/dose twice daily; max 20 mg/day	Sedation, hyperactivity, confusion, depression Avoid abrupt withdrawal
CLONIDINE (Catapres, Kapvay)	Alpha-2 adrenergic agonist	Hypertension, attention-deficit/hyperactivity disorder, Tourette syndrome, pain management	TAB, TDP: Doses vary based on clinical scenario	Dry mouth, sedation, hypotension, drowsiness, and skin reactions with patch Avoid abrupt withdrawal
CLORAZEPATE (Tranxene)	Benzodiazepine	Adjunctive therapy for partial seizures, anxiety	TAB: Initial dose of 3.75–7.5 mg/dose twice daily; increase of 3.75 mg/week; max 60 mg/day	Hypotension, drowsiness, dizziness (see also side effects of DIAZEPAM)
CLOTRIMAZOLE (Lotrimin, Mycelex)	Antifungal, topical, oral	Antifungal, <i>Candida albicans</i> infections	TAB, TOP: Cream: Apply twice daily for 2–4 weeks Oral: 10 mg/dose three to five times daily	Skin irritation, peeling, nausea, and vomiting with oral
CLOZAPINE (Clozaril, Fox Aclo)	Atypical antipsychotic	Refractory schizophrenia	TAB: Initial dose of 12.5–25 mg/dose once or twice daily	Hypotension, seizure, weight gain, sedation, extrapyramidal effects, agranulocytosis Patients must be registered prior to starting the medication
COLLOIDAL OATMEAL (Aveeno)	Skin treatment	Dry skin, itching	TOP: Add to bath or apply as needed	Allergic reaction
CORTICOTROPIN (Acthar, ACTH)	Corticosteroid, systemic	Infantile spasms and Lennox-Gastaut syndrome; many off-label uses	IV, IM, SQ: Doses vary based on clinical scenario	Glucose in urine, hypertension, cataracts, brittle bones, altered behavior, immunosuppression
CYPROHEPTADINE (Periactin)	Histamine (H ₁) antagonist	Allergies, migraines, appetite stimulation, spasticity, urticaria	TAB, LIQ: 0.25 mg/kg/day divided two to three times daily; max 16 mg/day	Weight gain, nausea, gastrointestinal irritation, dry mouth, somnolence
DANTROLENE SODIUM (Dantrium)	Skeletal muscle relaxant	Spasticity in cerebral palsy or spinal cord injury, malignant hyperthermia prevention	CAP, LIQ, IV: Initial dose of 0.5 mg/kg/dose twice daily; increase of 0.5 mg/kg/dose every week; max 2 mg/kg/dose two to four times daily Malignant hyperthermia: 2.5 mg/kg/dose	Weakness, drowsiness, lethargy, dizziness, tingling sensation, nausea, diarrhea, hepatotoxicity

(continued)

Table C.1. (continued)

Medication	Category	Use(s)	Standard applications	Side effects
DESIPRAMINE (Norpramin)	Tricyclic antidepressant	Depression, anxiety, attention-deficit/hyperactivity disorder, neuropathic pain	TAB: Not recommended in <12 yo; 0.5–2.5 mg/kg/dose twice daily; max 150 mg/day	Hypotension, dizziness, constipation, somnolence, dry mouth, blurred vision Increased suicidal risks in children and adolescents
DEXAMETHASONE (Decadron)	Corticosteroid, glucocorticoid	Anti-inflammatory or immunosuppressive used in multiple diseases like airway edema, chemotherapy nausea/vomiting, asthma exacerbation, cerebral edema, croup, bronchopulmonary dysplasia	TAB, LIQ, IV: Doses vary based on clinical scenario	Short-term use: headache, mood changes, hypertension or edema Long-term use: osteoporosis, weight gain, increased risk of infection, Cushing's syndrome, glaucoma and thinning skin
DEXTROAMPHETAMINE (Dexedrine, Dextrostat, ProCentra)	Stimulant	Attention-deficit/hyperactivity disorder, narcolepsy	CAP, LIQ, TAB: Initial dose of 2.5–5 mg once daily; max 40 mg/day	Insomnia, restlessness, decreased appetite, irritability, headache, abdominal cramps, decreased appetite, potential for abuse
DIAZEPAM (Valium, Diastat)	Benzodiazepine	Sedation, aggression, anxiety, spasticity, seizures, status epilepticus	TAB, LIQ, IV, SUPP: Doses vary based on clinical scenario	Sedation, weakness, depression, ataxia, memory disturbance, difficulty handling secretions and chewing/swallowing foods, paradoxical reactions (e.g., anxiety, agitation), respiratory and cardiac depression, rash, low white blood cell count
DIPHENHYDRAMINE (Benadryl)	Antihistamine	Sedation, allergies, hives, extrapyramidal symptoms, motion sickness	CAP, TAB, TOP, LIQ, IV: Not recommended <2 yo; 5 mg/kg/day divided three to four times daily; max 300 mg/day	Sedation, insomnia, dry mouth, dizziness, euphoria, gastrointestinal upset, paradoxical excitation
DULOXETINE (Cymbalta)	Antidepressant (norepinephrine serotonin reuptake inhibitor)	Depression, neuropathy, fibromyalgia, anxiety	CAP: ≥7 yo: Initial dose of 30 mg/dose once daily; increase to 60 mg after 2 weeks; max 120 mg/day	Dry mouth, nausea, diaphoresis, headache, insomnia, fatigue Increased suicidal risks in children and adolescents
DUODERM	Skin treatment	Skin ulcers/sores, second-degree burns, minor abrasions	TOP: Apply topically to site	Allergic reaction to tape or gel formula
ERYTHROMYCIN (E.E.S.)	Antibiotic, prokinetic agent	Used against staphylococcal infection, strep throat, and mycoplasma infections; used for gastro dysmotility, acne	CAP, TAB, LIQ, IV, TOP: Doses vary based on clinical scenario	Nausea, vomiting, diarrhea, cardiac dysrhythmias, drug interactions Topical: Skin dryness, peeling, skin irritation
ESCITALOPRAM (Lexapro)	Antidepressant (selective serotonin reuptake inhibitors)	Depression, anxiety, obsessive-compulsive disorder, panic disorder	TAB, LIQ: >12 yo: Initial dose of 10 mg/dose once daily; max 20 mg/day	QTc prolongation Increased suicidal risks in children and adolescents
ESOMEPRAZOLE (Nexium)	Proton pump inhibitor	Treatment or relief of ulcers, gastroesophageal reflux disease (GERD), erosive esophagitis associated with GERD	TAB, CAP, LIQ: Doses vary based on clinical scenario	Abdominal pain, diarrhea, nausea, flatulence, increased appetite, taste changes, headache

Medication	Category	Use(s)	Standard applications	Side effects
ETHOSUXIMIDE (Zarontin)	Anti-seizure medication	Absence seizures	CAP, LIQ: 10 mg/kg/dose twice daily usual dose; max 1.5 g/day	Sedation, unsteady gait, anorexia, rash, stomach distress, blood dyscrasias
FAMOTIDINE (Pepcid)	H ₂ antagonist	Gastroesophageal reflux, ulcers	CAP, TAB, LIQ, IV: 0.5 mg/kg/dose twice daily with meals; max 80 mg/day	Headache, dizziness, constipation, diarrhea
FELBAMATE (Felbatol)	Anti-seizure medication	Lennox-Gastaut syndrome; also effective in generalized and secondary generalized seizures, partial seizures	TAB, LIQ: 15–45 mg/kg/day divided three to four times daily	Anorexia, vomiting, insomnia, headache, rash, risk of life-threatening hepatitis and aplastic anemia
FERROUS SULFATE (Fer-In-Sol)	Nutritional supplement	Iron supplementation	TAB, LIQ: 1–3 mg/kg/dose twice daily	Constipation, dark stools, stomach cramps
FEXOFENADINE (Allegra)	Antihistamine	Treat allergies	TAB, LIQ, CAP, ODT: 6 mo–2 yo: 15 mg twice daily 2–11 yo: 30 mg twice daily ≥12 yo: 180 mg daily	Dizziness, headache
FLUCONAZOLE (Diflucan)	Antifungal	Treatment or prophylaxis of susceptible fungal infections, including oral and vaginal <i>C. albicans</i> infections	TAB, LIQ, IV: Doses vary based on clinical scenario	Dizziness, headache, rash, nausea, hepatotoxicity, drug interactions
FLUOXETINE (Prozac)	Antidepressant (selective serotonin reuptake inhibitor)	Depression, self-injurious behavior, Tourette syndrome, obsessive-compulsive disorder, anxiety, bulimia, panic disorder	TAB, CAP, LIQ: Safety and efficacy in children have not been established	Anxiety, agitation, sleep disruption, decreased appetite, seizures Increased suicidal risks in children and adolescents
FLUTICASONE (Flonase)	Corticosteroid	Used for asthma, allergic rhinitis	INH, INS: Doses vary based on clinical scenario	Throat irritation, upper respiratory tract infections, oral thrush
FOSPHENYTOIN (Cerebyx)	See PHENYTOIN; intravenous substitute for phenytoin	See PHENYTOIN	See PHENYTOIN	See PHENYTOIN
FUROSEMIDE (Lasix)	Diuretic, loop	Diuresis	TAB, LIQ, IV: 1 mg/kg/dose given one to four times daily; max 6 mg/kg/dose	Electrolyte abnormalities
GABAPENTIN (Neurontin)	Anti-seizure medication	Adjunctive therapy in partial and secondarily generalized seizures, neuropathic pain	CAP, TAB, LIQ: 3–15 mg/kg/dose divided three times daily; max 2,400 mg/day	Sedation, dizziness, unsteady gait, emotional instability Avoid abrupt withdrawal
GLYCEROL PHENYLBU-TYRATE (Ravicti)	Urea cycle disorder agent	Chronic management of urea cycle disorders	LIQ: Doses vary depending on scenario	Headache, skin rash, abdominal pain
GLYCOPYRROLATE (Robinul)	Anticholinergic	Decreases drooling in cerebral palsy	TAB, IV: Oral: 40–100 mcg/kg/dose every 3–4 hours as needed Injection: 4–10 mcg/kg/dose every 3–4 hours as needed	Rapid heart rate, orthostatic hypotension, drowsiness, blurred vision, dry mouth, constipation

(continued)

Table C.1. (continued)

Medication	Category	Use(s)	Standard applications	Side effects
GUANFACINE (Tenex, Intuniv)	Alpha-2 agonist	Hypertension, attention-deficit/hyperactivity disorder, Tourette syndrome	TAB: Doses vary depending on scenario	Dry mouth, sedation, hypotension, headache, nausea Avoid abrupt withdrawal
HALOPERIDOL (Haldol)	Antipsychotic, typical	Self-injurious behavior, Tourette syndrome, severe agitation, psychosis	TAB, LIQ, IV, IM: Doses vary depending on scenario	Extrapyramidal effects, hypotension, nausea, vomiting, electrocardiogram changes, neuroleptic malignant syndrome, lower seizure threshold in epilepsy, anticholinergic effects, tardive dyskinesia
HYDROCORTISONE (Cortizone)	Corticosteroid, topical	Eczema, dermatitis	TOP: Apply thin film two to four times daily	Skin irritation, dryness, rash
HYDROCORTISONE/ POLYMYXIN B/ NEOMYCIN (Cortisporin)	Corticosteroid + antibiotic, topical	Steroid-responsive skin conditions with secondary infection	TOP: Apply sparingly and massage into skin two or three times daily	Local irritation
IBUPROFEN (Advil, Motrin)	Nonsteroidal anti-inflammatory (NSAID)	Inflammatory diseases and rheumatoid disorders including juvenile rheumatoid arthritis, mild to moderate pain, fever, dysmenorrhea, migraines; also used for PDA closure in neonates	CAP, TAB, LIQ, IV: Doses vary depending on scenario	Gastrointestinal irritation, rash, dizziness, increased bleeding risk Caution in ulcer and renal patients
IMIPRAMINE (Tofranil, Janimine)	Tricyclic antidepressant	Depression, enuresis, neuropathy	CAP, TAB: Doses vary depending on scenario	Dry mouth, drowsiness, constipation, electrocardiogram abnormalities, increased blood pressure, urinary retention Increased suicidal risks in children and adolescents
INDOMETHACIN (Indocin)	NSAID	Inflammatory diseases and rheumatoid disorders; also used for PDA closure in neonates	CAP, LIQ, IV: 1–4 mg/kg/day; max 200 mg/day	Gastrointestinal irritation, rash, dizziness, increased bleeding risk Caution in ulcer and renal patients
ISOTRETINOIN (Accutane, Claravis)	Skin treatment	Severe acne	CAP: 0.2–1 mg/kg/dose twice daily	Dry mucous membranes, photosensitivity, dry skin, retinoid dermatitis, teratogen Patients must be registered prior to starting the medication
LAMOTRIGINE (Lamictal)	Anti-seizure medication	Adjunct or monotherapy for a variety of seizures, bipolar disorder	TAB, LIQ: Doses vary depending on scenario	Sedation, dizziness, ataxia, headaches, nausea, vomiting, severe and potentially life-threatening skin reactions
LANOLIN/PETROLATUM/ VITAMINS A & D (A&D Ointment)	Skin treatment	Diaper rash	TOP: Apply thin film at each diaper change	Allergic reaction

Medication	Category	Use(s)	Standard applications	Side effects
LANSOPRAZOLE (Prevacid)	Proton pump inhibitor	Treatment or relief of ulcers, GERD; adjuvant therapy in the treatment of <i>Helicobacter pylori</i> -associated gastritis	TAB, CAP, LIQ, ODT: Doses vary depending on scenario	Abdominal pain, nausea, flatulence, increased appetite, headache, fatigue, rash
LEVOALBUTEROL (Xopenex)	See ALBUTEROL	See ALBUTEROL	INH: Doses vary depending on scenario	See ALBUTEROL
LEVOCARNITINE	See CARNITINE	See CARNITINE	See CARNITINE	See CARNITINE
LEVETIRACETAM (Keppra)	Anti-seizure medication	Adjunctive therapy in a variety of seizure types, migraine prophylaxis	TAB, LIQ, IV: Initial dose of 10 mg/kg/dose twice daily; max 60 mg/kg/day or 3,000 mg/day	Somnolence, nausea, anorexia, dizziness, behavior changes, irritability
LEVOFLOXACIN (Levaquin)	Antibiotic, fluoroquinolone	See CIPROFLOXACIN	TAB, LIQ, IV: 8–10 mg/kg/dose once daily	See CIPROFLOXACIN
LEVOTHYROXINE (Synthroid, Levoxyl, Unithroid)	Thyroid product	Hypothyroidism	TAB, IV: <1 yo: 6–15 mcg/kg/dose once daily 1–5 yo: 5–6 mcg/kg/dose once daily 6–12 yo: 4–5 mcg/kg/dose once daily >12 yo: 2–3 mcg/kg/dose once daily	Heart palpitations, nervousness, tremor, excessive sweating, diarrhea, weight loss
LINDANE (Kwell)	Antiparasitic, topical	Scabies and lice	TOP: Doses vary depending on scenario	Seizure risk in small children with overuse
LISDEXAMFETAMINE (Vyvanse)	Stimulant	Attention-deficit/hyperactivity disorder	CAP, CHEW: 6–17 yo: 20–70 mg once daily in the morning; start 20–30mg each morning	Appetite suppression, insomnia, tachycardia, anxiety, headache, irritability
LITHIUM CARBONATE (Eskalith, Lithobid)	Antipsychotic	Mood stabilizer, bipolar disorder, depression	CAP, TAB, LIQ: 15–60 mg/kg/day divided in three to four doses; max 1,800 mg/day	Sedation, confusion, seizures, rash, hypothyroidism, diarrhea, muscle weakness, gastrointestinal irritation, renal dysfunction, tremor
LOPERAMIDE (Imodium)	Antidiarrheal	Treatment of acute diarrhea, traveler's diarrhea	CAP, LIQ, TAB: Doses vary depending on scenario	Abdominal cramps, constipation, nausea
LORATADINE (Claritin)	Antihistamine H ₁ antagonist	Allergies, urticaria	CAP, TAB, LIQ: 2–5 yo: 5 mg daily ≥6 yo: 10 mg daily	Sedation, dry mouth, headache
LORAZEPAM (Ativan)	Benzodiazepine	Anxiety, status epilepticus, agitation, sedation, antiemetic	TAB, LIQ, IV, IM: 0.05 mg/kg/dose every 4–8 hours as needed; max 4 mg/dose	Sedation, weakness, depression, unstable gait, memory disturbance
MAGNESIUM HYDROXIDE/ALUMINUM HYDROXIDE (Mylanta)	Antacid, laxative	Antacid for reflux; also helps treat constipation	LIQ: 2–4 teaspoons with meals and at bedtime	Abdominal pain, constipation, nausea, vomiting Caution in renal patients

(continued)

Table C.1. (continued)

Medication	Category	Use(s)	Standard applications	Side effects
METHYLPHENIDATE/ DEXMETHYLPHE- NIDATE (Concerta, Daytrana, Metadate, Metadate CD, Metadate ER, Methylin, Methylin ER, Ritalin, Focalin, Focalin XR)	Stimulant	Attention-deficit/hyperactivity disorder	CAP, LIQ, TAB, TDP: Doses vary depending on scenario	Appetite suppression, insomnia, arrhythmia, anxiety, headache, irritability
METHYLPREDNISOLONE (Solu Medrol)	Corticosteroid	Reduction of airway inflammation during acute asthma attacks, inflammatory conditions, many others	TAB, IV: 0.5 mg/kg/dose to 1 mg/kg/dose four times daily; max 60 mg/day	Headache, mood changes, hypertension or edema, osteoporosis, weight gain, increased risk of infection, Cushing's syndrome, glaucoma, thinning skin
METOCLOPRAMIDE (Reglan)	Prokinetic agent	Antireflux, increases gastric emptying	TAB, LIQ, ODT, IV: 0.025–0.125 mg/kg/dose divided four times daily; max 10 mg/dose	Dystonia, drowsiness, sedation, anxiety, leukopenia, muscle stiffness, tardive dyskinesia
MICONAZOLE (2%; e.g., Monistat)	Antifungal, topical	Antifungal, <i>C. albicans</i> infections	TOP: Apply twice daily	Skin irritation, peeling, pruritis
MINERAL OIL (e.g., Alpha Keri [dry skin], Fleet mineral oil enema [constipation])	Skin treatment, laxative	Emollient for dry skin; oral liquid or enema for constipation	LIQ, TOP: Doses vary depending on scenario	Allergic reaction (topical), nausea, and diarrhea (oral)
MINERAL OIL/PETROLA- TUM/LANOLIN (Nivea, Lubriderm)	Skin treatment	Emollient for dry skin, constipation	TOP: Apply as needed	Allergic reaction
MONTELUKAST (Singulair)	Leukotriene receptor antagonist	Asthma, allergies	TAB, CHEW, LIQ: 6 mo–5 yo: 4 mg daily 6–14 yo: 5 mg daily >15 yo: 10 mg daily	Headache, altered behavior, eosinophilia
MUPIROCIN (2%; Bactroban)	Antibiotic, topical	Antibiotic for impetigo, secondary infections of skin ulcers, burns	TOP: Apply sparingly three times daily; may cover with gauze	Burning, itching, pain at site of application
NALOXONE (Narcan)	Opioid antagonist	Opiate antagonist for treatment of self-injurious behavior	IV, INS: Doses vary depending on clinical scenario	Dependent on formulation given
NALTREXONE (Revia)	Opioid antagonist	Opiate antagonist for treatment of self-injurious behavior	TAB: Safety and efficacy in <18 yo have not been established	None in opioid-free individuals
NORTRIPTYLINE (Pamelor, Aventyl)	Tricyclic antidepressant	Depression, neuropathic pain, nocturnal enuresis, attention-deficit/hyperactivity disorder	CAP, TAB, LIQ: Doses vary depending on scenario	Dry mouth, drowsiness, constipation, electrocardiogram abnormalities, mania, sedation Increased suicidal risks in children and adolescents

Medication	Category	Use(s)	Standard applications	Side effects
NYSTATIN (Mycostatin)	Antifungal	Treatment of yeast and thrush infections in the mouth and gastrointestinal tract	TOP, LIQ: Doses vary depending on scenario	Diarrhea, redness, skin irritation, gastrointestinal upset
OLANZAPINE (Zyprexa)	Antipsychotic, atypical	Treatment of the manifestations of psychotic disorders, Tourette syndrome, anorexia nervosa, autism spectrum disorder	TAB, CAP, IV, IM: Initial dose of 2.5 mg/dose once daily, max 20 mg/day	Edema, weight gain, hyperglycemia, somnolence, orthostatic hypotension, increase in lipids, dizziness, tremor Increased suicidal risks in children and adolescents
OMEPRAZOLE (Prilosec)	Proton pump inhibitor	Treatment or relief of ulcers, GERD; adjuvant therapy in the treatment of <i>H. pylori</i> -associated gastritis	LIQ, CAP, TAB: Doses vary depending on scenario	Abdominal pain, diarrhea, nausea, flatulence, increased appetite, taste changes, headache
OXCARBAZEPINE (Trileptal)	Anti-seizure medication	Generalized tonic-clonic, complex partial, and simple partial seizures as both adjunctive and monotherapy	TAB, LIQ: 4–5 mg/kg/dose twice daily; max 2,400 mg/day	Ataxia, dizziness, gastrointestinal irritation, headache, somnolence, tremor, vision disturbances, hyponatremia
OXYBUTYNIN (Ditropan)	Antispasmodic agent, urinary	Antispasmodic for neurogenic bladder	TAB, LIQ: 0.2 mg/kg/dose two to four times daily; max 15 mg/day	Palpitations, drowsiness, dizziness, insomnia, dry mouth, nausea, vomiting, constipation, urinary hesitancy or retention, blurred vision, decreased tears, decreased sweating
PAROXETINE (Paxil)	Antidepressant (selective serotonin reuptake inhibitor)	Depression, obsessive-compulsive disorder, anxiety disorders, self-injurious behavior	TAB, LIQ: 10–20 mg/dose once daily; max 60 mg/day	Somnolence, headache, insomnia, nausea, constipation, decreased appetite, sexual dysfunction Increased suicidal risks in children and adolescents
PENICILLIN (Pen-VK)	Antibiotic	Treats strep throat	TAB, LIQ: 6.25–12.5 mg/kg/dose, four times daily	Allergic reactions, diarrhea, nausea
PERMETHRIN (Nix, Elimite)	Antiparasitic, topical	Scabies and lice	TOP: Doses vary depending on scenario	Pruritis, hypersensitivity, burning, stinging, rash
PETROLATUM/MINERAL OIL/WAX/ALCOHOL (Eucerin)	Skin treatment	Emollient for dry skin, itching	TOP: Apply as needed	Allergic reaction
PHENOBARBITAL (Luminal)	Anti-seizure medication	Generalized tonic-clonic, simple partial, and secondarily generalized seizures	CAP, TAB, LIQ, IV: 0.5–25 mg/kg/dose twice daily	Paradoxical hyperactivity, sedation, learning difficulties, behavioral difficulties, irritability, unsteady gait, respiratory depression
PHENYTOIN (Dilantin)	Anti-seizure medication	Generalized tonic-clonic and complex partial seizures	CAP, CHEW, LIQ, IV: Doses vary depending on scenario	Swelling of gums, excessive hair growth, rash, coarsening of facial features, possible adverse effects on learning and behavior, nystagmus and unsteady gait with toxic levels, blood dyscrasias, decreased bone density

(continued)

Table C.1. (continued)

Medication	Category	Use(s)	Standard applications	Side effects
POLYETHYLENE GLYCOL 3350 (MiraLax)	Laxative	Treatment of acute and chronic constipation	POWDER: 17 yo and older: Dissolve one capful (17 g) in 4–8 oz. of liquid; take once daily Younger than 17 yo: Dose adjusted under the advice of a qualified medical practitioner	Nausea, cramping, flatulence, diarrhea, rash
PREDNISOLONE (Prelone)	Corticosteroid, systemic	Reduction of airway inflammation during acute asthma attacks, inflammatory conditions, nephrotic syndrome	TAB, LIQ: Doses vary depending on scenario	Headache, mood changes, hypertension or edema, osteoporosis, weight gain, increased risk of infection, Cushing's syndrome, glaucoma, thinning skin
PREDNISONE (Deltasone)	Corticosteroid, systemic	Reduction of airway inflammation during acute asthma attacks, inflammatory conditions	TAB, LIQ: Doses vary depending on scenario	Headache, mood changes, hypertension or edema, osteoporosis, weight gain, increased risk of infection, Cushing's syndrome, glaucoma, thinning skin
PREGABALIN (Lyrica)	Anticonvulsant	Fibromyalgia, neuropathic pain, partial-onset seizures	CAP, LIQ: Safety and efficacy in <18 yo have not been established	Dizziness, drowsiness, blurred vision
PRIMIDONE (Mysoline)	Anti-seizure medication	Generalized tonic-clonic and complex partial seizures	TAB, LIQ: Doses vary depending on scenario	Drowsiness, dizziness, nausea, vomiting, leucopenia, systemic lupus like syndrome, nystagmus, personality change (<i>see also side effects of PHENOBARBITAL</i>)
QUETIAPINE (Seroquel)	Antipsychotic, atypical	Bipolar disorder, psychosis, depression, autism spectrum disorder	TAB, LIQ: >10 yo: 25 mg twice daily; max 600 mg/day	Hypertension or hypotension, hyperlipidemia, weight gain, gastrointestinal irritation, somnolence, tremor, extrapyramidal effects, dizziness, asthenia Increased suicidal risks in children and adolescents
RANITIDINE (Zantac)	Histamine H ₂ antagonist	Gastroesophageal reflux, ulcers	CAP, TAB, LIQ, IV: Doses vary depending on scenario	Headache, dizziness, constipation, diarrhea
RISPERIDONE (Risperdal)	Antipsychotic, atypical	Self-injurious behavior, psychosis, Tourette syndrome, aggression, pervasive developmental disorders	TAB, LIQ: 0.25–0.5 mg/dose twice daily; max 10 mg/day	Hypotension, sedation, dizziness, movement disorder, headache, constipation, weight gain, urinary retention, agranulocytosis, hyperprolactinemia, gynecomastia
SELENIUM SULFIDE (2.5%; Selsun Blue)	Skin treatment	Scalp conditions (dandruff or seborrhea)	TOP: Apply to wet scalp twice a week as needed	Skin irritation, dry or oily scalp, hair loss, and discoloration
SERTRALINE (Zoloft)	Antidepressant (selective serotonin reuptake inhibitors)	Depression, anxiety, obsessive-compulsive disorder, posttraumatic stress syndrome	TAB, LIQ: Safety and efficacy in <18 yo have not been established Initial dose of 25–50 mg/dose once daily; max 200 mg/day	Somnolence, headache, agitation, sleep disruption, decreased appetite, nausea, diarrhea, tremors, sweating, seizures Increased suicidal risks in children and adolescents

Medication	Category	Use(s)	Standard applications	Side effects
SODIUM PHENYLBUTYRATE (Buphenyl)	Hyperammonemia treatment; ammonium detoxicant	Adjunct for urea cycle disorder	TAB, TOP: Doses vary depending on scenario	Metabolic abnormalities, abdominal pain, nausea, vomiting
THEOPHYLLINE (Theodur, Uniphyll)	Respiratory agent	Bronchodilator; may be used in conjunction with other treatments for acute or chronic asthma	CAP, TAB, LIQ, IM, IV: Doses vary depending on scenario	Nausea, vomiting, stomach pain, gastroesophageal reflux, anorexia, nervousness, tachypnea
THIORIDAZINE (Mellaril)	Antipsychotic, typical	Self-injurious behavior, psychosis	TAB, LIQ: Doses vary depending on scenario	Drowsiness, hypotension, movement disorder, electrocardiogram abnormalities, retinal abnormalities, QTc prolongation
THIOTHIXENE (Navane)	Antipsychotic, typical	Self-injurious behavior, psychosis	CAP, LIQ: ≥12 yo: 2 mg/dose three times daily; max 30 mg/day	Tardive dyskinesia, neuroleptic malignant syndrome, rapid heart rate, hypotension, drowsiness, bone marrow suppression
TIAGABINE (Gabitril)	Anti-seizure medication	Adjunct for partial seizures	TAB: ≥12 yo: Initial dose of 4 mg once daily; max 32 mg/day	Dizziness, headache, sleepiness, central nervous system depression, memory disturbance, unsteady gait, emotionality, tremors, abdominal pain
TOLNAFTATE (Tinactin)	Antifungal, topical	Antifungal, ringworm	TOP: Apply small amount of cream or powder to affected area two to three times a day for 2–4 weeks	Skin irritation
TOPIRAMATE (Topamax)	Anti-seizure medication	Refractory partial seizures, Lennox-Gastaut syndrome, migraine prophylaxis	TAB, CAP: Initial dose of 0.5–1.5 mg/kg/dose twice daily; max 15 mg/kg/day	Edema, language problems, abnormal coordination, depression, difficulty concentrating, fatigue, dizziness, unsteady gait, sleepiness, weight loss, somnolence, weakness, nystagmus
TRIHEXYPHENIDYL (Artane)	Anticholinergic, drug-induced dystonic reactions	Dystonia reactions in cerebral palsy	TAB, LIQ: ≥2 yo: Initial dose of 0.05–0.1 mg/kg/dose twice daily	Tachycardia, skin rash, agitation, confusion, gastrointestinal disturbances, blurred vision
TRIAMCINOLONE (Kenalog)	Corticosteroid	Eczema, dermatitis	TOP: Apply thin film two to four times daily	Skin irritation, rash, dryness
TRIMETHOPRIM/SULFAMETHOXAZOLE (TMP/SMX) (Bactrim, Septra)	Antibiotic	Treatment or prophylaxis of susceptible infections, including urinary tract infections, otitis media, and sinusitis	TAB, LIQ, IV: 4–10 mg/kg/dose of TMP twice daily	Bone marrow suppression, allergic reactions, photosensitivity, gastrointestinal irritation, rash
VALPROIC ACID (Depakene, Depacon, Depakote)	Anti-seizure medication, mood stabilizer	Myoclonic, simple absence, and generalized tonic-clonic seizures, Lennox-Gastaut syndrome, infantile spasms; also used to treat aggression and mood disorders, bipolar disorder, impulsive aggression, intermittent explosive disorder, migraine prophylaxis	CAP, LIQ, TAB, IV: Doses vary depending on scenario	Hair loss, weight loss or gain, abdominal distress, tremor, agranulocytosis, low platelet count, teratogen, hepatotoxicity, pancreatitis

(continued)

Table C.1. (continued)

Medication	Category	Use(s)	Standard applications	Side effects
VENLAFAXINE (Effexor, Effexor XR)	Antidepressant (norepinephrine-selective reuptake inhibitors)	Depression, anxiety, attention-deficit/hyperactivity disorder, panic disorder	TAB, CAP: Initial dose of 12.5 mg/dose once daily, max 75 mg/day	Hypertension, diaphoresis, weight loss, gastrointestinal irritation, insomnia, tremor, dizziness, somnolence, headache Increased suicidal risks in children and adolescents
ZINC OXIDE (Desitin)	Skin treatment	Diaper rash	TOP: Apply three or four times daily after diaper change or bath	Allergic reaction
ZINC OXIDE/COD LIVER OIL/LANOLIN/ PETROLATUM (Caldesene ointment)	Skin treatment	Diaper rash	TOP: Apply three or four times daily after diaper change or bath	Allergic reaction
ZIPRASIDONE (Geodon)	Antipsychotic, atypical	Bipolar disorder, psychosis, agitation, Tourette syndrome	CAP, IV, IM: Doses vary depending on scenario	Orthostatic hypotension, gastrointestinal irritation, hyperglycemia, weight gain, extrapyramidal effects, insomnia, somnolence, QTc prolongation, blood dyscrasias
ZONISAMIDE (Zonegran)	Anti-seizure medication	Adjunctive therapy in partial seizures, infantile spasms, and Lennox-Gastaut syndrome	CAP: ≥16 yo: 50 mg/dose twice daily; max 400 mg/day	Somnolence, dizziness, ataxia, loss of appetite, gastrointestinal discomfort, headache, agitation/irritability, confusion, rash, visual disturbances
Key: CAP, capsule; CHEW, chewable; IM, intramuscular injection; INH, inhalation; INS, intranasal; IT, intrathecal; IV, intravenous; LIQ, liquid suspension or solution; ODT, oral dissolvable tablet; SQ, subcutaneous injection; SUPP, suppository; TAB, tablet; TDP, transdermal patch; TOP, topical creams, ointments, or powders; mo, month(s) old; yo, year(s) old.				

Table C.2. Commonly used medications, alphabetized by drug class

Drug class	Generic name	Brand name
Acne	ISOTRETINOIN	Accutane, Claravis
Attention-deficit/hyperactivity disorder	AMPHETAMINE SALTS	Adderall
	ATOMOXETINE	Strattera
	BUPROPION	Wellbutrin
	CLONIDINE ER	Kapvay
	DEXTROAMPHETAMINE	Dexedrine, Dextrostat, ProCentra
	GUANFACINE ER	Intuniv
	LISDEXAMFETAMINE	Vyvanse
	METHYLPHENIDATE/DEXMETHYLPHENIDATE	Concerta, Daytrana, Focalin, Metadate, Methylin, Ritalin
Analgesic	ACETAMINOPHEN	Tylenol
Antacid	CALCIUM CARBONATE	Calcium carbonate
	MAGNESIUM HYDROXIDE/ALUMINUM HYDROXIDE	Mylanta
Anti-anxiety	BUSPIRONE	Buspar
Antibiotic	AMOXICILLIN	Amoxil
	AMOXICILLIN/CLAVULANIC ACID	Augmentin
	AZITHROMYCIN	Zithromax
	CEFDINIR	Omnicef
	CEFPODOXIME	Cefpodoxime
	CEPHALEXIN	Keflex
	CIPROFLOXACIN	Cipro
	CLARITHROMYCIN	Biaxin
	ERYTHROMYCIN	E.E.S
	HYDROCORTISONE/POLYMYXIN B/NEOMYCIN (TOPICAL)	Cortisporin
	LEVOFLOXACIN	Levaquin
	MUPIROCI (TOPICAL)	Bactroban
	PENICILLIN	Pen-VK
	TRIMETHOPRIM/SULFAMETHOXAZOLE (TMP/SMX)	Bactrim, Septra
Anticholinergic	BENZTROPINE	Cogentin
	GLYCOPYRROLATE	Robinul
	TRIHENXYPHENIDYL	Artane
Anticonvulsant/ anti-seizure medication	ACETAZOLAMIDE	Diamox
	CARBAMAZEPINE	Tegretol
	ETHOSUXIMIDE	Zarontin
	FELBAMATE	Felbatol
	FOSPHENYTOIN	Cerebyx
	GABAPENTIN	Neurontin
	LAMOTRIGINE	Lamictal
	LEVETIRACETAM	Keppra
	OXCARBAZEPINE	Trileptal
	PHENOBARBITAL	Luminal
	PHENYTOIN	Dilantin
	PREGABALIN	Lyrica
	PRIMIDONE	Mysoline

(continued)

Table C.2. (continued)

Drug class	Generic name	Brand name
	TIAGABINE	Gabitril
	TOPIRAMATE	Topamax
	VALPROIC ACID	Depakote, Depakene, Depacon
	ZONISAMIDE	Zonegran
Antidepressant	AMITRIPTYLINE	Elavil
	BUPROPION	Wellbutrin
	CITALOPRAM	Celexa
	CLOMIPRAMINE	Anafranil
	DESIPRAMINE	Norpramin
	DULOXETINE	Cymbalta
	ESCITALOPRAM	Lexapro
	FLUOXETINE	Prozac
	IMIPRAMINE	Tofranil, Janimine
	NORTRIPTYLINE	Pamelor, Aventyl
	PAROXETINE	Paxil
	SERTRALINE	Zoloft
	VENLAFAXINE	Effexor
Antidiarrheal	LOPERAMIDE	Imodium
Antifungal	FLUCONAZOLE	Diflucan
	CLOTRIMAZOLE	Lotrimin, Mycelex
	MICONAZOLE	Monistat
	NYSTATIN	Mycostatin
	TOLNAFTATE	Tinactin
Antihistamine/allergy relief	CETIRIZINE	Zyrtec
	CYPROHEPTADINE	Periactin
	DIPHENHYDRAMINE	Benadryl
	FEXOFENADINE	Allegra
	LORATADINE	Claritin
Antihypertensive	CLONIDINE	Catapres
	GUANFACINE	Tenex
Antiparasitic	LINDANE	Kwell
	PERMETHRIN	Nix, Elimite
Antipsychotic	ARIPRAZOLE	Abilify
	CHLORPROMAZINE	Thorazine
	CLOZAPINE	Clozaril, Fox Aclo
	HALOPERIDOL	Haldol
	LITHIUM CARBONATE	Lithobid, Eskalith
	OLANZAPINE	Zyprexa
	QUETIAPINE	Seroquel
	RISPERIDONE	Risperdal
	THIORIDAZINE	Mellaril
	THIOTHIXENE	Navane
	ZIPRASIDONE	Geodon

(continued)

Table C.2. (continued)

Drug class	Generic name	Brand name
Antipyretic	ACETAMINOPHEN	Tylenol
Antireflux	ESOMEPRAZOLE	Nexium
	FAMOTIDINE	Pepcid
	LANSOPRAZOLE	Prevacid
	METOCLOPRAMIDE	Reglan
	OMEPRAZOLE	Prilosec
	RANITIDINE	Zantac
Antispasticity/muscle relaxant	BACLOFEN	Lioresal
	BOTULINUM TOXIN A	Botox
	DANTROLENE SODIUM	Dantrium
	OXYBUTYNIN	Ditropan
Antiviral	ACYCLOVIR	Zovirax
Appetite stimulator	CYPROHEPTADINE	Periactin
Benzodiazepine	ALPRAZOLAM	Xanax
	CLONAZEPAM	Klonopin
	CLORAZEPATE	Tranxene
	DIAZEPAM	Valium, Diastat
	LORAZEPAM	Ativan
Bronchodilators	ALBUTEROL	Ventolin
	LEVALBUTEROL	Xopenex
	THEOPHYLLINE	Theo-Dur, Uniphyll
Corticosteroids	BUDESONIDE	Pulmicort, Rhinocort
	CORTICOTROPIN	Acthar, ACTH
	DEXAMETHASONE	Decadron
	FLUTICASONE	Flonase
	HYDROCORTISONE	Cortizone
	HYDROCORTISONE/POLYMYXIN B/NEOMYCIN (TOPICAL)	Cortisporin
	METHYLPREDNISOLONE	Solu Medrol
	PREDNISOLONE	Prelone
	PREDNISON	Deltasone
	TRIAMCINOLONE	Kenalog
Diuretic	ACETAZOLAMIDE	Diamox
	CHLOROTHIAZIDE	Diuril
	FUROSEMIDE	Lasix
Electrolyte supplementation	CALCIUM CARBONATE	Calcium carbonate
	CALCIUM GLUCONATE	Calcium gluconate
Laxative	MAGNESIUM HYDROXIDE/ALUMINUM HYDROXIDE	Mylanta
	MINERAL OIL	Fleet mineral oil enema
	POLYETHYLENE GLYCOL 3350	MiraLax
Leukotriene receptor antagonist	MONTELUKAST	Singulair
Nonsteroidal anti-inflammatory drugs (NSAIDs)	IBUPROFEN	Advil, Motrin
	INDOMETHACIN	Indocin

(continued)

Table C.2. (continued)

Drug class	Generic name	Brand name
Nutritional supplementation	CARNITINE	Carnitor
	FERROUS SULFATE	Fer-In-Sol
	LEVOCARNITINE	Carnitor
Opioid antagonist	NALOXONE	Narcan
	NALTREXONE	Revia
Prokinetic agents	ERYTHROMYCIN	E.E.S
	METOCLOPRAMIDE	Reglan
Proton pump inhibitors	ESOMEPRAZOLE	Nexium
	LANSOPRAZOLE	Prevacid
	OMEPRAZOLE	Prilosec
Skin treatment	COLLOIDAL OATMEAL	Aveeno
	DUODERM	DuoDERM
	ISOTRETINOIN	Accutane, Claravis
	LANOLIN/PETROLATUM/VITAMINS A & D	A&D Original Ointment
	MINERAL OIL	Alpha Keri
	MINERAL OIL/PETROLATUM/LANOLIN	Nivea, Lubriderm
	PETROLATUM/ALCOHOL/MINERAL OIL/WAX	Eucerin
	SELENIUM SULFIDE	Selsun Blue
	ZINC OXIDE	Desitin
	ZINC OXIDE/COD LIVER OIL/PETROLATUM/LANOLIN	Caldesene ointment
Stimulants	AMPHETAMINE SALTS	Adderall, Adderall XR
	DEXTROAMPHETAMINE	Dexedrine, Dextrostat, ProCentra
	METHYLPHENIDATE/DEXMETHYLPHENIDATE	Concerta, Daytrana, Focalin, Metadate, Methylin, Ritalin
	LISDEXAMFETAMINE	Vyvanse
Thyroid product	LEVOTHYROXINE	Synthroid, Levoxyl, Unithroid
Urea cycle disorder	GLYCEROL PHENYLBUTYRATE	Ravicti
	SODIUM PHENYLBUTYRATE	Buphenyl
Urology	OXYBUTYNIN	Ditropan

Table C.3. Commonly used medications, alphabetized by brand name

Brand name	Generic name
A&D Original Ointment	LANOLIN/PETROLATUM/VITAMINS A and D
Abilify	ARIPIPRAZOLE
Accutane	ISOTRETINOIN
ACTH	CORTICOTROPIN
Acthar	CORTICOTROPIN
Adderall	AMPHETAMINE SALTS
Advil	IBUPROFEN
Allegra	FEXOFENADINE
Alpha Keri	MINERAL OIL
Amoxil	AMOXICILLIN
Anafranil	CLOMIPRAMINE

(continued)

Table C.3. (continued)

Brand name	Generic name
Artane	TRIHENXYPHENIDYL
Ativan	LORAZEPAM
Augmentin	AMOXICILLIN/CLAVULANIC ACID
Aveeno	COLLOIDAL OATMEAL
Aventyl	NORTRIPTYLINE
Bactrim	TRIMETHOPRIM/SULFAMETHOXAZOLE (TMP/SMX)
Bactroban 2%	MUPIROCI
Benadryl	DIPHENHYDRAMINE
Biaxin	CLARITHROMYCIN
Botox	BOTULINUM TOXIN A
Buphenyl	SODIUM PHENYLBUTYRATE
Buspar	BUSPIRONE
Caldesene ointment	ZINC OXIDE/COD LIVER OIL/LANOLIN/PETROLATUM
Carnitor	LEVOCARNITINE
Catapres	CLONIDINE
Celexa	CITALOPRAM
Cerebyx	FOSPHENYTOIN
Cipro	CIPROFLOXACIN
Claravis	ISOTRETINOIN
Claritin	LORATADINE
Clozaril	CLOZAPINE
Cogentin	BENZTROPINE
Concerta	METHYLPHENIDATE
Cortizone	HYDROCORTISONE
Cortisporin	HYDROCORTISONE/POLYMYXIN B/NEOMYCIN
Cymbalta	DULOXETINE
Dantrium	DANTROLENE SODIUM
Daytrana	METHYLPHENIDATE
Decadron	DEXAMETHASONE
Deltasone	PREDNISONE
Depacon	VALPROIC ACID
Depakene	VALPROIC ACID
Depakote	VALPROIC ACID
Desitin	ZINC OXIDE
Dexedrine	DEXTROAMPHETAMINE
Dextrostat	DEXTROAMPHETAMINE
Diamox	ACETAZOLAMIDE
Diastat	DIAZEPAM (RECTAL)
Diflucan	FLUCONAZOLE
Dilantin	PHENYTOIN
Ditropan	OXYBUTYNIN
Diuril	CHLOROTHIAZIDE
DuoDERM	DUODERM

(continued)

Table C.3. (continued)

Brand name	Generic name
Effexor	VENLAFAXINE
Elavil	AMITRIPTYLINE
Elimite	PERMETHRIN
E.E.S.	ERYTHROMYCIN
Eskalith	LITHIUM CARBONATE
Eucerin	PETROLATUM/ALCOHOL/MINERAL OIL/WAX
Felbatol	FELBAMATE
Fer-In-Sol	FERROUS SULFATE
Fleet Mineral Oil Enema	MINERAL OIL
Flonase	FLUTICASONE
Focalin	DEXMETHYLPHENIDATE
Fox Aclo	CLOZAPINE
Gabitril	TIAGABINE
Geodon	ZIPRASIDONE
Haldol	HALOPERIDOL
Imodium	LOPERAMIDE
Indocin	INDOMETHACIN
Intuniv	GUANFACINE ER
Janimine	IMIPRAMINE
Kapvay	CLONIDINE ER
Keflex	CEPHALEXIN
Keppra	LEVETIRACETAM
Klonopin	CLONAZEPAM
Kwell	LINDANE
Lamictal	LAMOTRIGINE
Lasix	FUROSEMIDE
Levaquin	LEVOFLOXACIN
Lexapro	ESCITALOPRAM
Lioresal	BACLOFEN
Lithobid	LITHIUM CARBONATE
Lotrimin	CLOTRIMAZOLE
Lubiderm	MINERAL OIL/PETROLATUM/LANOLIN
Luminal	PHENOBARBITAL
Lyrica	PREGABALIN
Mellaril	THIORIDAZINE
Metadate	METHYLPHENIDATE
Methylin	METHYLPHENIDATE
MiraLax	POLYETHYLENE GLYCOL 3350
Monistat 2%	MICONAZOLE
Motrin	IBUPROFEN
Mycelex	CLOTRIMAZOLE
Mycostatin	NYSTATIN
Mylanta	MAGNESIUM HYDROXIDE/ALUMINUM HYDROXIDE

(continued)

Table C.3. (continued)

Brand name	Generic name
Mysoline	PRIMIDONE
Narcan	NALOXONE
Navane	THIOTHIXENE
Neurontin	GABAPENTIN
Nexium	ESOMEPRAZOLE
Nivea	MINERAL OIL/PETROLATUM/LANOLIN
Nix	PERMETHRIN
Norpramin	DESIPRAMINE
Omnicef	CEFDINIR
Pamelor	NORTRIPTYLINE
Paxil	PAROXETINE
Pen-VK	PENICILLIN
Pepcid	FAMOTIDINE
Periactin	CYPROHEPTADINE
Prelone	PREDNISOLONE
Prevacid	LANSOPRAZOLE
Prilosec	OMEPRAZOLE
ProCentra	DEXTROAMPHETAMINE
Prozac	FLUOXETINE
Pulmicort	BUDESONIDE
Ravicti	GLYCEROL PHENYLBUTYRATE
Reglan	METOCLOPRAMIDE
Revia	NALTREXONE
Rhinocort	BUDESONIDE
Risperdal	RISPERIDONE
Ritalin	METHYLPHENIDATE
Robinul	GLYCOPYRROLATE
Selsun Blue 2.5%	SELENIUM SULFIDE
Septra	TRIMETHOPRIM/SULFAMETHOXAZOLE (TMP/SMZ)
Seroquel	QUETIAPINE
Singulair	MONTELUKAST
Solu Medrol	METHYLPREDNISOLONE
Strattera	ATOMOXETINE
Synthroid	LEVOTHYROXINE
Tegretol	CARBAMAZEPINE
Tenex	GUANFACINE
Theo-Dur	THEOPHYLLINE
Thorazine	CHLORPROMAZINE
Tinactin	TOLNAFTATE
Tofranil	IMIPRAMINE
Topamax	TOPIRAMATE
Tranxene	CLORAZEPATE
Triamcinolone	TRIAMCINOLONE

(continued)
